Herein comes the insight of a kind of artist or diviner; an intuition of the combination and phases that natural processes may follow. As Sir Clifford says, the divination is, in part, a natural gift, which means that the ready and accurate diagnostician is like the poet—born and not made; but unless built up by incessant touch with things, and an acquired familiarity with their ways, the natural gift will be barren. Nor is that all; in human medicine, at any rate, we have also to construct a third method, that of verbal examination, a kind of experiment as fallacious as it is indispensable. Record of present feelings is almost as slippery as record of the past, and it needs education of the patient as well as of the doctor. The writer goes on to point out a fact, most obvious to every practising physician, that it is difficult to sift and also to verify the complaints of a patient and the records of his parentage and, of course, this is more and more difficult the earlier the stage of the malady; for the earlier the stage of a certain series the less its differentiation from the incipient stages of other series. Early symptoms are often vague and indefinable; not only so, but morbid conditions have all something, and many of them much, in common. However, it is patent that the detection of the beginnings of disease involves the existence of much insight and intensive training on the part of the practitioner, and education on the part of the patient. But the writer does not call attention to perhaps the greatest obstacle to the successful prosecution of the form of preventive medicine. This is that patients must be educated to consult a doctor when seemingly trivial symptoms appear. It will take a great deal of educational propaganda to persuade a working man to seek the advice of the physician when the earliest symptoms of disease show themselves. And yet the obstacles are not insuperable, and in spite of all difficulties preventive internal medicine has a good chance of succeeding.

Allbutt says further that, if we are to be successful in our search for the beginnings of disease, we must gain some insight into molecular physics. He also notices that immunity is the key to large provinces of clinical medicine. After referring at some length to the enzymes, to the rich results of the study of the blood, chemical, mor-

phological, and serological, to the marvelous system of the hormones, to renal chemistry, and to intestinal toxins, he ends by stating that as physicians we call for three classes of men of science: first, the pure scientist, who lives his own inner disinterested life, unoccupied with any relations to things outside his study; secondly, a middleman, who as engineer can adapt theory to practice; thirdly, the modern practitioner, well educated in principles, taught to handle ideas, aware of the direction from which knowledge may flow, and openminded enough to accept it, subject always to the contingencies which he best knows how to manage.

INFLUENZAL PNEUMONIA.

THERE is still much difference of opinion as to the etiology of influenza and as to whether what is known as influenzal pneumonia is a complication of the disease or a stage in the process of its development. In the *Edinburgh Medical Journal* for July and August, 1920, Professor Karl Petren of the Internal Clinic at the University of Lund, Sweden, writes on influenzal pneumonia and its treatment. With regard to the nature of this disease he states that his general impression is that it must, to a very marked degree, be considered a specific one, and he believes that influenza should be regarded as both a general infection and a local infection of the mucous membrane of the respiratory tract. According to this view, instead of pneumonia and bronchitis being complications, the bronchitis and pneumonia of influenza are only different degrees of development of the same local morbid affection. From a close comparative study of influenza, Petren arrives at the conclusion that it is a specific disease; that influenzal pneumonia is part of the disease process, and finds its explanation in quantitative factors which determine the varying degree of development of the local morbid affection in the respiratory tract.

Petren says that if the recent pandemic be compared with that of 1889-90, the same characteristic features from both the nosographical and epidemiological points of view will be found. The most marked difference is the high degree of cyanosis in the latest outbreak. But it seems evident that the last epidemic has been much more severe than those of former times, and, if this is the case, it can be understood that in the former epidemics the tendency to massive involvement of the lungs was not so great, and, consequently, cyanosis was a much less prominent feature. He holds that an acute infectious disease which appears only at certain epochs well separated from each other and which then reappears with identical clinical manifestations and anatomical changes, is, as all experience in pathology has taught, caused by a specific microorganism, typical of and specific to just this disease. Such a microorganism must be constant in the disease, and if a method of finding it had been discovered, it would be found in every case. If influenzal pneumonia is a specific disease, it cannot be the consequence of an accidental secondary infection, for it is impossible that the same disease should be the effect of different infections in different cases; this would be contrary to all pathological experience. The question of the virus common to influenza and to influenzal pneumonia, Petren considers from exactly the same point of view. Consequently, he believes that all the different microorganisms that have been found in influenzal pneumonia have nothing to do with that virus which is the true cause of the pneumonia; and that as a matter of fact they are only secondary in respect of the pneumonia. From the same point of view, he regards it as quite impossible that the bacillus of Pfeiffer should be the true cause of influenza, since that microorganism has not been found in all the cases. He is in accord with many observers in his skepticism regarding Pfeiffer's bacillus. The point of his paper is that influenzal pneumonia is a phase of the disease and caused by a virus which has not yet been isolated.

ACUTE, FOCALLY DISSEMINATE, NONPURULENT (LYMPHOCYTIC), TOXIC-INFECTIOUS, EPIDEMIC POLIOENCEPHALOMYELITIS.

DOCTOR Tobler of the Basle Pathological Institute evidently believes in giving to diseases their full titles, for this is his name for encephalitis lethargica. In an article on this subject, which appears in the *Schweizerische medizinische Wochenschrift* for June 10, 1920, i, 24, he concludes an account of the pathological finds of 10 cases and follows with an elaborate discussion of the intimate nature of the process and its relations to other cerebral affections. The long title facilitates the comparison with other maladies. Among the affections discussed are African sleeping sickness, rabies, certain affections peculiar to various animals, such as Borna's disease of horses, acute poliomyelitis, polioencephalitis of the vertex, and grippal encephalitis. Special attention is called to differentiating the latter. In the author's experience grippal encephalitis is usually cortical by preference and hemorrhagic, while lethargic encephalitis is neither. But as far back as 1895 Nauwerck found grippal encephalitis with lesions in the basilar ganglia and there are in fact transitional cases in which a diagnosis will necessarily be very difficult. For example, in one case of epidemic encephalitis a cerebral hemorrhage was placed in association with a complicating hemorrhagic pneumonia. In the pathological institute the two affections, which had prevailed side by side, ceased at the same time, which was rather a striking coincidence. The author believes that while in the clinic the two affections may at times be readily confounded, the autopsy will readily clear up the confusion so that our own health officers should encourage autopsies in all cases of cerebral death in which one or the other of these two maladies could be the cause.

THE FEBRICULAS.

PROFESSOR RICALDONI contributes an interesting paper on this subject to the *Anales de la Faculdad de Medicina* (Montevideo), March-April, 1920, v,

3-4. He first disposes of the false febriculas or simple hyperthermias, and also of simulation of fever by warming the thermometer, etc. Of the true febriculas the best known is that due to tuberculosis. Menstrual fever is less a result of simple menstruation than an indication of some deep-seated affection in which the act of menstruation determines a crisis of fever. Thus if a woman develops febricula or actual fever during or just before menstruation there is a likelihood of tuberculosis. So-called osteogenic fever is seen in growing children and in some cases may best be regarded as simple hyperthermia. Leopold-Levi regards so-called osteogenic fever as really of endoctrine motivation. Canalicular or cavitary fever is seen in connection with slight infections in various ducts and cavities. A good example is seen in the febricula of chronic appendicitis which indicates an abortive or larvated attack of inflammation in the canal. A rare type of febricula is the renal, of which the author narrates a case. The presence of slight temperature led to a regrettable error in diagnosis, the actual difficulty having been uremia. Of endocrinic febriculæ the hyperthyroid is the best known, and in such cases tuberculosis may be suspected from the tachycardia and other phenomena. Of hematic fevers the chlorotic deserves mention. "Crypto-cancerous fever" is a well known phenomenon and the author relates several cases in visceral cancer. Other febriculæ comprise the prehemorrhagic, verminous, nervous, septicemic and post-infectious types.

Recovery from Fifteen Grains of Cocaine by the Mouth.

Bonjour of Lausanne reports in the *Revue médicale de la Suisse romande* for June, 1920, xli, 6, the case of a homosexual man aged 25 who out of spite against some person not named swallowed the contents of a gram bottle of cocaine. As he was employed in a laboratory there was no trouble in getting the drug. The dose was swallowed at 11 P.M. During the night there was total insomnia and mild agitation with diminution of general sensibility, both superficial and deep. The lower extremities had a dead feel. At 8 A.M. he was weak and ill and summoned the author. Two hours later he dressed and went to his office. The symptoms were remarkably mild, the pulse being apparently normal. There was no elevation of blood pressure from vasoconstriction; there was no "cocaine jag" and no increased reflex activity such as is common among snuffers. There had been no convulsive stage with subsequent motor paralysis. The sole symptoms were agitation and hypesthesia. There was no irregularity of the pulse, no ultimate lowering of tension; in fact, the symptoms agreed with those which follow the ingestion of small doses.

News of the Week.

Another Examination for Commission in Regular Army.—The Secretary of War has directed that another examination be held October 25 to 31, to determine the eligibility for appointment of applicants for commission in the Medical and Dental Corps of the Regular Army. Persons of the following classes who served as officers of the United States Army at some time between April 6, 1917, and June 4, 1920, are eligible to take this second examination: (a) Those who for any good reason did not apply and were not authorized to take the July examinations. (b) Those who were authorized to take the July examinations, but who for some good reason were unable to appear before the examining board. (c) Those who were authorized to take the July examinations and who appeared before examining boards, but who for some good reason of their own volition or through illness or accident failed to complete the examination. (d) Those examined during the July examination who were found disqualified on account of physical defects which have been removed by operation or which do not exist at the time of the October 25 examination. Applications should reach the War Department on or before October 9.

Campaign Against Narcotic Drugs in Canada.—Federal health authorities of the Dominion of Canada announce gratifying results in the campaign being waged against the drug evil. Dr. J. A. Amyot, assistant medical director of the Department of Health, who has just returned to Montreal from an extended trip across the country, states that there has been a falling off in the number of drug addicts. Several attempts to form opium rings have been thwarted, and it is intended to put into force early in the autumn the opium and narcotic drug act passed at the last session of the Canadian Parliament. Under this act wholesale druggists, manufacturers or dealers, are required to obtain a license to deal in these drugs; for this an annual fee is charged. All retail druggists who manufacture narcotic drugs or preparations containing the same are required to obtain a license; all druggists, other than those who manufacture, and all physicians, veterinary surgeons, and dentists are required to make a declaration that they are engaged in the sale or distribution of these drugs. It is also required that all druggists, whether wholesale or retail, and all manufacturers, keep a record of their receipts, together with a record of the quantity manufactured, and a record of their sales. Such records must be kept, in prescribed form, in a special book for the purpose.

Vital Statistics in Vienna.—With the assistance of the Austrian Government, the American Red Cross Commission in Vienna has compiled statistics which show that while in 1912 the birth rate was 19.1 per 1,000 and the death rate 15.4, in 1919 these rates were respectively 13.1 and 22.3. The death rate from tuberculosis has doubled, as has that from other infectious diseases. From the tabulated statistics of the non-military causes of deaths from 1912 to 1919 it is found that cancer, kidney, and stomach diseases have remained nearly stationary since the last peace year, that diseases of the liver have grown less with the lessening of food, and that contagious diseases have diminished with the closing of means of communication between Vienna and the outside world.

Typhus Research Hospital in Poland.—At the request of the League of Red Cross Societies a large typhus research hospital will be operated in

connection with the new American Red Cross hospital recently established in Wilno under the direction of Major F. W. Black.

Further Affliction for Fiume.—It is rumored, according to news from this center of the spectacular, that Fiume has discovered four cases of bubonic plague. Theaters have been closed and other local precautions taken. Steamers and trains, however, continue to run.

Vaccination of Passengers to the United States.—Orders have been issued by the United States Public Health Service to all officers in Europe to permit no third class passengers to depart for the United States without having been vaccinated against smallpox. Dr. Rupert Blue will remain in Paris all winter for the purpose of perfecting the organization of the health service, with an office in every large port in Europe, in order to minimize the danger of smallpox, typhus, and other diseases being brought to this country from overseas.

"Red Tape" in Liquor and Narcotic Laws.—At the opening session of the National Association of Retail Druggists recently held in St. Louis, plans were suggested for the elimination of the "red tape" involved in the handling of alcohol and narcotics. Among other points noted it was brought out that a druggist, in filling a prescription for whiskey, is required to sign his name forty-two times and that alcohol can only be obtained sixty days after application is made. It was stated that the regulations governing the sale of narcotics are so complicated, and change so often that druggists never know when they are complying with the law.

Not Struck by the "H. C. L."—We are reminded, apropos of the coming Red Cross drive, that about the only thing that has not advanced in price during the last few years is membership in the American Red Cross. It is still one dollar.

Drink Record Low for 1919.—According to a recent announcement by the Department of Commerce the consumption of wines and liquors in the United States in 1919 was less per capita than during any year since 1870. In 1870 the quantity was 7.70 gallons per capita, rising to 22.79 gallons in both 1907 and 1911 and falling to 9.17 gallons last year. The total consumption of wines and liquors in 1919 was 992,394,720 gallons, compared with 1,701,827,271 gallons or 15.05 gallons per capita in 1918.

New Insignia for the Medical Department.—According to recent War Department orders the collar insignia for officers of the different corps of the Medical Department of the army will be the Caduceus with the following letters superimposed for the different corps: The Medical Administrative Corps (formerly the Sanitary Corps), "A"; Contract Surgeons, "C"; Dental Corps, "D"; Army Nurse Corps, "N"; Veterinary Corps, "V."

Rest House for Nurses.—A rest house for nurses who have served with the Army, Navy, Red Cross or United States Public Health organization has been opened at Bayshore by the Red Cross. Nurses taking government vocational training courses, those being trained under the Red Cross scholarship arrangement and other nurses who wish to avail themselves of the benefits of the rest house will also be eligible. Application should be made to Miss Florence M. Johnson, director of the Atlantic Division Nursing Department.

New State Hospital for Wisconsin.—Plans have been submitted to the Wisconsin State Architect's office for the new State hospital to be erected on the campus of the University of Wisconsin. The completed hospital, as planned, will include two groups of buildings, in addition to the first group, which is to be started this year. The completed institution will have a capacity of one thousand beds.

Chemical Exposition.—The Sixth National Exposition of Chemical Industries opened at the Grand Central Palace, New York City, on September 20, with 460 exhibitors occupying four floors.

Poliomyelitis Reappears.—Three cases and one death from anterior poliomyelitis were reported to the New York City Health Commissioner on September 24. Two weeks ago the Commissioner issued a warning to physicians to be on guard for the disease, which had appeared at Boston. There have been forty-eight cases, with eight deaths, in New York City since the beginning of the year.

Dr. W. N. Thayer, who for a number of years has been physician to the Eastern New York State Reformatory, at Napanoch, has been appointed warden of that institution.

Dr. Nathaniel Read Norton has removed his office to 111 East Seventy-eighth Street, New York City.

Chicago Still At It.—Another Chicago physician moves up to the front ranks of "booze" prescription writers. When arraigned before the dry officials to show cause why his permit to write liquor prescriptions should not be revoked, this disciple of Æsculapius acknowledged having written 700 liquor prescriptions in four days and that on one day he topped the mark with 308. His permit was temporarily withdrawn pending decision as to its revocation.

Encouraging Influenza Outlook.—The United States Public Health Service gives out the encouraging forecast that there have been no indications of a return of influenza this year. While cases are reported each November and May, it is not expected that the disease will be so widespread or so severe this year as in 1919.

Vaccination of School Children Urged.—Health Commissioner Royal S. Copeland urges that every child in New York City be vaccinated against smallpox before entering school, and that adults who have not been inoculated during the past eight or ten years be vaccinated. About sixty cases of smallpox have been reported here during the past three months.

Red Cross Roll Call.—The fourth annual roll call of the American Red Cross will be held Nov. 11 to 25.

Drug Clinics Closed.—The New York State Narcotic Drug Control Commission, through Commissioner Walter R. Herrick, has ordered the closing of all clinics established by the commission in sixteen cities of the State. The reason assigned is the refusal of hospitals to receive drug addicts to complete their cures. This action followed a confer-

ence with Federal officials, who declared that the clinics, without subsequent hospital treatment, become nothing more than "drug emporiums" for addicts.

The American Electrotherapeutic Association, at its thirtieth annual meeting held in Atlantic City Sept. 14-17, elected the following officers for the ensuing year: *President,* Dr. Byron Sprague Price, New York City; *Vice-Presidents,* Dr. Virgil C. Kinney, Wellsville, N. Y.; Dr. C. M. Sampson, M. C., U. S. A.; Dr. Charles Collins, Washington, D. C.; Dr. Douglas A. Cater, East Orange, N. J.; Dr. W. T. Johnson, Philadelphia; *Trustees,* Dr. Frank B. Granger, Boston; Dr. Frederick H. Morse, Boston; Dr. W. M. Clark, Philadelphia; Dr. E. C. Titus, New York; Dr. William Martin, Atlantic City; Dr. Frederic de Kraft, New York; *Secretary and Registrar,* Dr. A. Bern Hirsh, New York City; *Treasurer,* Dr. J. Willard Travell, New York City.

Medical Society Meetings.—The Medical Association of the Southwest will hold its fifteenth annual meeting at Wichita, Kan., Nov. 22, 23 and 24, under the presidency of Dr. E. F. Day of Arkansas City, Kan.

Charitable Bequests.—By the will of Colonel Thomas W. Bradley of Walden, N. Y., formerly Representative in Congress, the sum of $5,000 each is bequeathed to St. Luke's Hospital, Newburgh, and Thrall Hospital, Middletown.

Obituary Notes.—DR. ELISHA AVERETT JENKINS, of Brooklyn, N. Y., formerly of Natural Bridge, Va., died at Saranac Lake, N. Y., September 18, at the age of forty-six.

DR. JOHN HENRY COTTER, of Brooklyn, N. Y., died recently of cardiac disease, at the age of fifty-two. He was graduated from Albany Medical College in 1894.

Dr. EDGAR MORTON WOOLF died at his home in this city on Sept. 26 of pneumonia. He was born in 1888 and was graduated from the Long Island College Hospital in 1909.

Obituary.

GEORGE MOREWOOD LEFFERTS, M. D.

NEW YORK.

Dr. GEORGE M. LEFFERTS died at his country residence, Katonah, N. Y., on Sept. 21, after a number of years of invalidism, at the age of 74 years. He was born in Brooklyn, Feb. 24, 1846, and was educated at the College of the City of New York. His medical degree was conferred by the College of Physicians and Surgeons in 1870. After serving his term as hospital interne he went to Vienna to study laryngology and rhinology, returning to New York to take up the practice of this specialty in 1873. The following year he was appointed clinical professor of laryngoscopy and diseases of the throat at the College of Physicians and Surgeons, Columbia University, professor of laryngology and rhinology at the same school in 1896, and emeritus professor in 1904. In 1910 he retired from practice. During his active professional life Dr. Lefferts was a member of the Medical Societies of the County and State of New York, the New York Academy of Medicine, and the American Laryngological Association.

Correspondence.

POTASSIUM NITRATE IN CANCER.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—I would beg the indulgence of a brief space to express my pleasure at finding the criticism of Dr. Robert Bell, in your issue of Sept. 11, contains so many points which coincide with my views regarding cancer. That the disease is dependent upon the condition of the blood is agreed upon by those who have given thought to the chemical constitution of this fluid, and it is reasonable to assume that dyscrasias of the body will follow when this medium is vitiated.

I remarked that the Doctor did not say what cancer is, and as he failed to state what particular condition of the blood produces the disease, I am unable to see why he throws discredit on my statement that "cancer is caused by an excess of sodium chloride in the blood and tissues of the body." Doctor Bell does not state why this is not so, but goes on to say that potassium nitrate, which I administer as a positive cure for cancer, is the heritage of some "old wife," and without any apparent beneficial result, so far as he could ascertain. Be this as it may, had the old lady in question given this remedy in accordance with the ionic theory of Arrhenius and in such a manner as to allow of a chemical reaction taking place between the potassium nitrate and the sodium chloride of the blood, thereby forming potassium chloride, the results in the cure of cancer would have been as astonishing as those I am now witnessing in company with other physicians. Anyone realizing the importance of osmosis would at a glance see why a concentrated solution of potassium nitrate would fail to pass into the cells or enter into a chemical combination sufficiently to form a new salt which the cells would take into their composition. In all probability the Doctor has reference to a saturated solution too concentrated for any other purpose than to cause an enteritis or a gastritis.

Doctor Bell seems not to regard those cases of cancer successfully treated by me with potassium nitrate, reported in my article in the MEDICAL RECORD for July 24, as worthy of comment, but fails to suggest any explanation for the results obtained. Nothing succeeds like success, and whether Dr. Bell believes it or not the fact remains that cancer is now being successfully cured by the use of potassium nitrate, not only in my own practice but by those physicians who are following the scheme of treatment of which I have written during the past three years.

With the kindliest of motives I would suggest that Dr. Robert Bell save himself some embarrassment in the future by taking advantage of the clinical material now under his charge in the Battersea Hospital, London, and making experiments with a solution of potassium nitrate sufficiently dilute to enter the cells, and thus prove whether I am right or not regarding the statement that this salt will cure cancer.

A new therapeusis has entered the field of medicine for which I claim priority. I was the first to give scientific reasons why an excess of sodium chloride in the blood and tissues of the body would cause cancer, and also the first to demonstrate that

the disease could be cured by the administration of potassium nitrate. Priority for the use of potassium nitrate by hypodermoclysis in the treatment of cancer also belongs to me. I am furthermore authority for the statement that there is no other salt to be found in nature which can take the place of potassium nitrate in the treatment of cancer, reasons for which were given in the MEDICAL RECORD of May 4, 1918.

From the experience I have gained, coupled with that of other physicians, I firmly believe that the day is not far distant when the medical profession will welcome this discovery as the true and only scientific method of treating cancer, without the use of the knife or other means which might palliate but not remove the cause of the disease, and I feel that when Dr. Bell realizes this he will be in the front rank as an advocate for the use of potassium nitrate in the treatment of cancer.

EDWARD PERCY ROBINSON, M.D.

452 FIFTH AVENUE.

UNNECESSARY NOISE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Of all the factors which tend to disturb the mental and physical equilibrium of men and women everywhere, and particularly in a large city like New York, there perhaps is none of more subtle and deadly potency than noise; and while there are many kinds and variations of noise, no one of which is to be especially condemned for its harmful influence, for it is a well-known fact that a noise which would be aggravating to one individual would appeal pleasurably to another, it is nevertheless true that all of these contribute in some measure to make up the common din that surrounds us on all sides during our waking and sleeping hours, with injurious effects that are in a general sense as needless as they are incalculable.

From a medical standpoint, the ill effect of noise upon a susceptible individual can only be compared to the cumulative and final result of a series of taps on a diseased organ which had its inception in some minor form of nervous disorder. The effects of noise upon the sick, and particularly upon any patient afflicted with any form of nervous trouble, are quite generally and thoroughly recognized, and the establishment of restrictive measures in and around hospitals, as well as the location of sanitariums in the most quiet and remote sections of the country, bear eloquent testimony not only to the beneficial results thus to be secured, but also to the vital importance and necessity of reducing to the lowest minimum possible the noises attending our daily life.

This is a matter of such pressing concern to the public in general that it would appear not only desirable but highly proper for the medical profession, through some one or all of its associated bodies, to formulate some definite action in conjunction with the civil authorities having in view the establishment of effective measures for the reduction and elimination of unnecessary noise, thereby contributing in no small degree to the public health and welfare.

JOHN COGHLAN, M. D.

137 EAST FIFTY-SECOND STREET,
NEW YORK.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, September 3, 1920.

Dangerous Drugs Regulations.—The British Home Secretary has given notice that under the Dangerous Drugs Act 1920, which came into operation on September 1, the import and export of opium, medicinal opium, morphine, diamorphine (heroin), cocaine, and ecgonine are prohibited except under license of the Secretary of State. The prohibition extends to the salts of morphine, diamorphine, cocaine, and ecgonine, and any preparation, admixture, extract, or other substance containing not less than one-fifth per cent. of morphine or one-tenth per cent. of cocaine, ecgonine, or diamorphine (heroin). Notice has also been given that on and after September 1 next the import and export of raw opium will be allowed only through the ports of London and Liverpool, which are the ports approved by the Board of Customs for the purpose.

Rate Aided Hospitals.—The proposal of the Ministry of Health to allow local authorities to aid hospitals out of the rates has by no means been received with universal favor. The following letter signed by a number of his Bedford constituents has been forward to the member of Parliament for that division. "As members of your constituency we are driven to send you our strong protest against the proposal to provide support for hospitals out of the rates. We are acquainted with the inadequate contributions of the hospital beneficiaries, the highly paid working classes. The Government, judged by the daily reports of the press, have become a mere squeeze committee to yield to every demand, call, or suggestion of the trade unions; the Prime Minister's time, which should be devoted to the interest of the whole nation and empire, is monopolized by them. Have citizens as such no rights? For many months the press has been filled page after page with the reports of the demands and reiterated demands of one section of the community. The time has come, is long overdue, when the socalled middle and upper classes will insist upon relief of their killing burdens." The above letter is expressive of the views of a large portion of the British population with regard to the maintenance of hospitals. It is perfectly true that the working classes are highly paid nowadays, and it is also true that they have not recognized their responsibility and duty toward the hospitals by assisting to support them in a manner commensurate with their increased earnings. This fact lends greater force to the suggestion that hospitals should be supported or largely supported by the institution of the pay or partial pay system. It is fair to all and tends to self respect and independence. It certainly is unfair that the new poor, the lower middle classes, should be taxed almost beyond endurance, while the working classes, comparatively affluent, should get off scot free. There is a fear that the Ministry of Health may become too much of a political body and lean toward those who possess the voting power.

Alcohol and the Body.—At the present time when the question of the value or otherwise of

alcohol as a beverage or drug is arousing intense interest, and is indeed in many countries, as in America, a nationaal question, the advice of the man of science is essential in order that the nation's policy with regard to liquor may be placed on a firm foundation. Personal prejudices and interests are apt to become so entangled with social and moral argument that confusion reigns. When the physiological effects of alcohol can be clearly defined from all points of view there will be a common body of fact to form a basis for discussion and wild statements will be materially and beneficially reduced. It cannot be said that scientific men have as yet defined the physiological effects of alcohol with sufficient definite lucidity. Among men of science there is no complete agreement on the subject. For example, the late Sir Victor Horsley held different views on the subject to those of Professor Karl Pearson and Sir Archdall Reid, and they were all first class scientific men. At the recent meeting of the British Association a somewhat important contribution to the subject was made in a joint paper presented by Miss May Smith and Dr. W. McDougall to the Psychology Section upon "The Mental Effects of Alcohol and Opium." Dr. McDouglall is a well-known psychologist, and it is in the interests of science and of society and morality that he has concentrated his knowledge and experience on the endeavor to elucidate some of the obscure points of this most important matter. The authors of the paper described a series of experiments they have made. They have by mechanical means tested attention and memory as affected by alcohol, both under normal conditions and in subjects suffering from fatigue. The results were that when the factors were in ordinary equilibrium the alcoholic intervention was found to be of a deteriorative character. In cases of fatigue, however, both powers were improved. They found that alcohol taken after a meal produced a much slighter deviation than in other circumstances. The full text of this paper is not available yet so that it is difficult to pass any estimate of its value from the summaries at hand. If sufficiently important it will be referred to at greater length in a later letter.

In connection with the influence of alcohol, Sir J. C. Bose, in the Botanic Section of the Association, provided perhaps the most delightful lecture of the entire week. He told how at his Botanic Institute in Calcutta he discovered that all plants reacted to stimulus, and their actions closely resembled those of human organisms under similar tests. By delicate instruments he had succeeded in making plants record their own movements. A carrot became intoxicated under alcohol, and the recording instrument indicated a line which from being straight, became erratic. Under chloroform or ether a plant became unconscious. He placed the normal rate of the growth of a plant at 100,000th part of an inch in a second. He claimed for his discoveries and particularly for certain magnifiers that they would be of great use to agriculturists, instancing that he had found that certain substances supposed to be harmful, if administered in very small quantities, tended to stimulate growth.

Remarkable Longevity.—The reputed age of Thomas Parr has been subjected to a good deal of destructive criticism, and it has been frankly denied that the Countess of Desmond, who is said to have broken a leg at the age of 119 by falling from an apple tree, reached the patriarchal age of something over 140. Consequently it is more than likely that the paragraph culled from the *Gentleman's Magazine* for May, 1781, and quoted by Mr. Henry J. Mead in the *Sunday Observer*, August 29, will be regarded by the skeptical with suspicion. The paragraph in question reads as follows: "In the churchyard at Ware on the south side of the church, is an altar tomb of brick with a blue marble slab inscribed to William Mead, M.D., who died October 28, 1652, aged 148 years and nine months.

War on Rats in Paris.—In a previous letter it was stated that plague had been reported in Paris and that the assumption was that it had been carried there by rats which abound in that city. According to the Paris correspondent of the Times, writing from Paris on August 26, an attempt is shortly to be made to exterminate the rats, estimated at 8,000,000 or more, which infest the Paris underworld, and by their presence endanger the health of the population. The urgency of this campaign has been manifested by a recent case of plague. All details of the campaign have been drawn up by a special staff at the Prefecture under the generalship of Professor Bordas. Another campaign against rats will soon be inaugurated in Great Britain, and is expected to be of wider range and better organized than the last.

Effect of a Shorter Working Day.—Professor F. S. Lee of Columbia University, New York, spoke at the recent meeting of the British Association on August 27 on "Some Phenomena of Industrial Fatigue." He said in part that the hourly output in physiological operations was practically always increased by a diminution of hours, but the effect on the total output depended on the balance between increased productive power and lessened hours of work. In the very severe tasks of the millmen in the tinplate manufacture Vernon found the total output to be 8.3 per cent. greater in the six-hour than in the eight-hour shift. But this lent no support to the argument for a universal six-hour day. What period, indeed, represented the most nearly universal optimum for a working day was still an open question. A comparison of the diurnal curves of the output of the eight and ten-hour factories investigated by the public health service showed that a conspicuous feature of work on the eight-hour plan was its steady maintenance of output in contrast to the fluctuations of output of the ten-hour plan. Each added contribution of observation and experiment appeared more and more to support the view that from the standpoint of physiological essentials the optimum working period was comparatively short, but varied in duration with the kind of work performed. Eight hours was probably too long for certain kinds of work and too short for others. A universal eight-hour day would be unscientific. Recess periods during the working spell nearly always resulted in increased hourly output and frequently increased output for the whole day.

Shell Shock Inquiry.—The constitution of the War Office Departmental Committee which has been set up by the Secretary of State for War, as a result of the motion of Lord Southborough in the House of Lords on April 28 last, for the appointment of a committee to inquire into the expert knowledge derived from the experiences of the late war with regard to shell shock has been officially announced. By its terms of reference the committee is appointed to consider the different types of hysteria and traumatic neurosis, commonly called "shell shock," to collate the expert knowledge derived by the service, medical authorities, and the medical profession from the experiences of the war with a view to recording for future use the ascertained facts as to its origin, nature, and remedial treatment, and to advise whether, by military training or education, some scientific method of guarding against its occurrence cannot be devised.

A Post-Graduate Course in Venereal Diseases.—A post-graduate course of instruction in the treatment of venereal diseases is to be given at the London Royal Free Hospital School of Medicine for Women. Arranged for the behoof of qualified medical women it will begin on September 13 and conclude on September 25. The Elizabeth Garrett Anderson Hospital and the London Lock Hospital are interested in the fixture.

Obituary.—The death occurred on August 26, at Sydenham, near London, of Dr. Henry Shackleton, the father of Sir Ernest Shackleton, the well-known explorer. Dr. Shackleton, who was 73 years of age, had been ill for some time. He was an Irishman, and resided in County Kildare until he came to London in 1885. Dr. Shackleton did not take up the study of medicine until comparatively late in life, but he became well known as an obstetric surgeon. He had been in practice at Sydenham since he first came to this country up to about four years ago when he retired.

4. Occupational Therapy for the Tuberculous.—F. H. Hunt holds that occupational therapy's chief aim is psychic, and that, based upon its psychic effect, it is applicable to all stages of tuberculosis, early and late, favorable and unfavorable, each case presenting its own problem. When, in occupational therapy, controlled exercise is added, and additional purpose has been brought in, physical upbuilding with enhanced immunity. While it is believed that results are most positively beneficial, only massive comparative statistics, not yet available, can answer the question as to the percentage of cases in which the desired object is accomplished, which, in its final analysis, is to induce the patient to remain long enough under treatment to receive the maximum benefit thereof.

8. Backache from the Viewpoint of the General Surgeon.—Moses Behrend says the back may be divided, theoretically, into the gynecological, the orthopedic, the neurological, the medical, and the surgical back. The surgical back refers especially to injuries which may result in a fracture of one or more spinal vertebræ and to injuries in the loin space, especially the kidneys. Injuries to the back may also occasionally cause traumatic inguinal hernia. The appendix is not to be forgotten in the consideration of backache. At times grave disease in the loin space, such as retroperitoneal sarcoma, may be retroactive, that is, in the early stages the pain may be referred to the anterior portion of the abdomen instead of to the back. Renal and gall-bladder calculi are to be considered. Ulcer of the duodenum and ulcer of the stomach on the anterior wall; the lesser curvature, or at the pylorus, rarely give rise to backache, but ulcers on the posterior wall of the stomach, especially those adherent to the pancreas and even to the parietal peritoneum, may cause backache burning in character. Syphilis, when it affects the liver, the author says, may give rise to a continual dragging sensation in the back.

6. Acute Cardiac Upsets, Occurring During or Following Surgical Operations.—Samuel A. Levine bases this paper on observations in nine surgical cases in which there had been some sort of circulatory upset or collapse during or following operations. Surgical shock is excluded from the study. The conditions were diagnosed by the surgeons as acute dilatation of the heart in some cases, and might very well have been similarly diagnosed in others had not the real nature of the disorder been discovered. In this study particular attention was paid to the mechanism of the heart beat, and in each instance this was found to be abnormal. Of the nine patients three had paroxysms of auricular tachycardia, four suddenly went into auricular fibrillation, and the other two had paroxysmal auricular flutter. Every patient had a high grade of auricular disturbance, and in all but two the condition was transient in nature, the normal rhythm subsequently being resumed. Graphic proof of the abnormal mechanism, obtained by taking electrocardiograms of six patients, and the clinical course of the other three, left no doubt as to the real nature of the disturbance. It is urged that well-defined terms which actually describe the abnormal mechanism be employed when possible, rather than the vague name "acute dilatation of the heart." Direct vagal pressure or ocular pressure proved successful in arresting all three of the cases of paroxysmal auricular tachycardia. Proper digitalis therapy controlled the course of the cases of paroxysmal auricular flutter and paroxysmal auricular fibrillation.

2. Chronic Abdominal Pain. Edward Beansly.
3. *X*-rays and the Appendix. R. Allen Bennett.
4. Anaesthesia in Tonsil and Adenoid Operations. Courtnay Yorke.

2. Chronic Abdominal Pain.—Edward Beansly, after calling attention to the difficulty encountered in determining the cause of pain, especially in the case of the viscera, says that in spite of all that has been learned from physiologists as to the innervation of the internal organs and the manner in which painful impressions arising within them are referred to definite skin areas supplied by corresponding somatic nerves, we are far from being able to assign to a definite organ many of the various internal pains for which patients seek explanation and relief. For the present clinical experience and circumstantial evidence must be relied upon. This is particularly the case with pains which are referred more or less vaguely to the abdomen. The classification of such pains as "acute" and "chronic" is ambiguous and misleading, because it confuses intensity with duration. The writer discusses the types of pain due to the several organs, the methods of diagnosis, gives special attention to appendicitis, viceroptosis and intestinal stasis, and exploratory operation.

5. Gastric Neuroses.—Alexander G. Brown. Jr., enumerates the various stomach conditions which are considered as gastric neuroses, and, after eliminating all changes in organic structure, gives the three following general avenues through which these conditions arise: (1) Nervous mechanism of the motor. secretory and sensory innervation of the stomach during its work. (2) The daily task given the stomach to do in quantity and quality of food. (3) The blood factors supplying the nervous, muscular and secretory structures of the stomach. The points which he particularly emphasizes are: that there is a large group of so-called stomach cases in which the violent misfunction may be and should be corrected before pathological conditions are produced; that this field of work is in the hands of the general practitioner; that such conditions should be investigated and "run down" or else gross pathology will result.

Resection of Rectal Cancer in a Youth of Twenty.—Botteselle reports this case, which is of a type of increasing frequency—rectal cancer in comparatively early life. Dr. Jerome M. Lynch is quoted as saying that but 4 per cent. of victims are under the age of 30. But one case is mentioned in which the age approximates that of the present patient; this was reported by Foisy and Rolland in 1916 in a youth of 21. Cancer is less frequent in Italy than in some of the countries nearer the north and this may explain the great infrequency of cases like the present in that country. In the United States Lilienthal and others have reported rectal cancer in youth in their teens. The author's patient was an artisan of negative family and personal history. On consultation it appeared that the symptoms had begun forty-five days before with difficult defecation. The passage was liquid and bloody. This was followed by a deceptive period of normal defecation and stools. The original symptoms then returned in an aggravated form and patient sought the clinic. He was found to be a man of excellent health, red haired and freckled, with well developed muscles and sound organs. An ulcerated, mobile tumor was felt in the right side of the rectum. It reached to within 2 cm. of the sphincter and was about 3 cm. in height. The presacral glands were felt enlarged, hard, and but slightly movable. The seroreactions of tuberculosis and syphilis were negative. There is no mention of an ante-operative diagnosis, but it was evidently malignant tumor which led to resection of the rectum. A low power examination under the microscope rapidly made the diagnosis. The operation was done in September and the patient was under observation until the following January. Retraction had taken place, and the author passed a bougie at intervals to oppose the rectal stenosis. Death came about from peritonitis, the exact mechanism of which is not apparent.

Sporadic and Epidemic Encephalitis.—Wieland sums up an article on this subject as follows: In regard to the epidemicity of encephalitis the motivation of influenza must be considered; and while no direct connection between the two diseases can be shown, an indirect one is possible. There are the possibilities of mixed infection and there may be strain of grippe virus which can produce encephalitis. While nearly all men are perdisposed to influenza, very few are to encephalitis. This predisposition, naturally extremely faint, is increased perhaps by influenza pandemics. But this is not the whole of the predisposition, for in some cases there has been no previous exposure to grippe. The pleomorphism and alternation of encephalitis is not as mysterious as it seems, for it can be accounted for by localization of the virus. Lethargy is only a matter of the focus attacked and is not the genius of the disease. In no previous conception of encephalitis has this question of focal symptoms been active. Economo, who is responsible largely for the essential quality of lethargy, has modified his conception by substituting the term "poliencephalitis hemorrhagica epidemica." The author regards the main distinction between epidemic and sporadic encephalitis as follows: the former is primarily of primary and epidemic incidence and the latter is mostly a sequela of various acute infectious diseases.

Actual State of Our Knowledge of Alimentary Anaphylaxis.—Laroche, Richet, Jr., and Saint Girons contribute this article and begin by citing the labors in this field of Arthus. Besredka, Rosenau and Anderson, Nobécourt, Richet, Wells and Osborne, and Lesne and Dreyfus. This refers only to major anaphylaxis, which

is seen especially after eggs, milk and mussels. It is expressed as anaphylactic shock. But with this form the authors are not here concerned. They are interested in petty anaphylaxis expressed as urticaria, pruritus and angioneurotic edema, asthma, etc. The leading writers on this form are Widal, Abrami, Brissaud and Joltrain, Pagniez and Pasteur Valery-Radot, Cordier (with special reference to asthma), Nast, Nathan, etc. Among affections studied from this viewpoint have been migraine and epilepsy. In the petty type authors speak of crises of anaphylaxis such as might explain any affection which occurs in serial paroxysms. Beyond this type we see chronic anaphylaxis especially in the response of certain infants to milk as studied recently by Barbier. Common to all anaphylaxis appears to be the sequence of emaciation. The greater the emaciation the more readily may anaphylaxis be produced. In the infant with chronic anaphylaxis the emaciation may, of course, be attributed to gastroenteric indigestion, but the failure of digestion and assimilation may itself be explained as a consequence of the anaphylaxis. The authors mention under the head of treatment that pepsine and pancreatine are both indicated to place the *primæ viæ* in favorable condition. The principal therapeutic recourse is injection of boiled milk subcutaneously to desensibilize the patient. The use of peptone in urticaria and even for drug anaphylaxis has given some surprising results.

Brazil-Medico.

June 19, 1920, xxxiv, 25.

Who Was the First to Describe the Socalled Korsakoff's Disease?—In a recently published graduation thesis of Rio University, written by Mourao Mattos, the author insists that the Brazilian alienist Coelho was the first to isolate this affection, and he would henceforth term the latter the "syndrome of Erico Coelho." The date at which the latter presented his contribution before the medical profession was May, 1886. Professor Fajardo, when he made a journey to Europe and learned of the new Korsakoff disease, got the impression that plagiarism from his chief, Coelho, had been committed. There are still other claimants, for, according to Dupre, no less a person than Charcot, mentioned the syndrome in the course of his "Thursday lectures," but no dates are mentioned nor any reference to a published article. It is conceivable that in an affection like alcoholic polyneuritis the coexistence of mental disorder may have been mentioned independently by several men. Charcot had noted amnesia in two alcoholic women with polyneuritis. Korsakoff spoke of oniric delirium superposed on a continuous amnesia. Coelho mentions as characteristic inability to coordinate ideas of the most banal kind, mental confusion and failure of memory, the latter being the most striking behavior; half an hour after a meal there would be no recollection of the event. Memory for long passed events might still be good. The claim of Coelho may be technically invalidated by the fact that he was writing primarily of beri-beric polyneuritis or probably of the general phenomenon of polyneuritis associated with mental disorders, irrespective of the particular motivation. But apparently a specific beri-beric form was not isolated until many years later. The claim of Coelho, as we understand it, is that he first pointed out the "polyneuritic psychosis" as a syndrome, irrespective of the cause.

Le Presse Médicale.

July 10, 1920, xxviii, 47.

Pernicious Anemia in Uremic Nephritis.—Aubertin and Yacoel state that the anemia of Bright's disease has long been known and has in part been explained by hydremia and dilution; but there is over and above a pernicious type which is able to destroy life of itself, and from which a hydremic component can be definitely excluded. Under what circumstances does this type occur? The authors cite cases in point. In one a girl of 21 developed a grippal nephritis which, despite the vegeto-lacteal diet, persisted after recovery from influenza. She was first seen in the fifth month by Vaquez after a profuse epistaxis. The most striking symptoms were profound anemia and dyspnea. Most of the petty signs of uremia were evident, including amaurosis. The dyspnea could be in part attributed to crepitant rales over both bases. The patient had not menstruated since the attack of grippe. There was slight cardiac hypertrophy. The amount of urine voided was satisfactory and even slightly excessive, with 1.5 gms. albumin, blood cells and a few granular casts. The uremia was 2.2 gms. and the coagulation time 8 min. 30 sec., the blood clotting poorly. The blood cell count gave 82 per cent. of neutrophile polynuclears; red cells 1,100,000. The complete diagnosis was pernicious anemia, albuminuric-azotemic nephritis without edema, and dry pericarditis. The patient responded to treatment for about two months, when oliguria suddenly developed, corresponding, perhaps, to terminal atrophy following nephritis. Death was not attended by convulsive phenomena nor did edema supervene. Autopsy revealed chronic nephritis with very adherent capsule and sclerosis of the cortex. The spleen and marrow of the long bones showed the alterations common to severe anemia. The nephritis and anemia had pursued a rapid course side by side. There was initial improvement in both conditions followed by recrudescence and fatal cachexia due to both syndromes acting in concert.

March, 1920, lxxiii, 3.

Child Mortality in the Belgian Congo.—This subject is of interest from several angles, including that of recolonization of Africa by American negroes. Dossin covers it with great thoroughness. He sketches the physical and mental development of the aboriginal infant. Natality is low at present from a mixture of causes. There is no reason why the women should not be more fertile than they are, but very large families —such as twelve children—are quite exceptional. The custom is to bear no further child until the present one is weaned, this taking about thirty months. The women, therefore, breed every three years or more, and there is quite a sentiment of Malthusianism about too many offspring, due in part to the superstition that a new baby means the death of the last one. The Church has combated this view with some success. Prostitution and immorality are universal and with this comes venereal disease and sterility and in general extinction of the desire for maternity. Limited figures are given which show remarkably low birth rates and a large percentage of still births. Concubinage and polygamy are common, but their effects on the birth rate are not stated. Syphilis and gonorrhea both seem on the increase. Artificial abortion has been practised from time immemorial. Among endemic diseases which tend to lower the birth rate are sleeping sickness, leprosy, and yaws. The constant movement of the native troops makes directly against natality. The child mortality is known to be high, due to a variety of causes, as ignorance of child hygiene, the causes of death being given in the order named: digestive disturbances, exposure which leads to respiratory affections due to nocturnal coolness, worm diseases with especial reference to the hookworm, convulsions, malaria, and other affections already mentioned. The youth of the mothers is naturally a condition favorable to high mortality.

Antiquity of the Term "Pedology."—The use of this term for child study is said to have been proposed in 1895 by Chrisman of Jena. Belgium is the pioneer country to push the systematic study of the subject, and before the recent war there were no less than three Belgian periodicals devoted to the new discipline, comprising *Les Annales Pédologiques*, *La Pedotechni*, and *Le Pedologium*. Pedological laboratories were established and the first session of an International Congress was held. It is of interest, however, to note that in 1518 a Latin volume was published, probably in Leipzig, with the title *Paidologia*. The book is one of the rarest and its very existence is ignored by the new school of pedologists. Dr. Blanco y Sanchez intimates that the contents of the work will be reproduced in the first volume of *Spanish-American Pedagogic Annals* soon to be issued as the organ of the new Spanish Society of Pedology.—*El Siglo Medicó.*

Book Reviews.

GRUNDRISS DER AUGENHEILKUNDE FÜR STUDIERENDE UND PRAKTISCHE AERZTE Von Prof. Dr. A. BRÜCKNER und Prof. Dr. W. MEISNER. Leipzig: Georg Thieme, 1920.

THE authors are respectively the director and first assistant of the Berlin University Eye Clinic and the work, a first edition, comprises 649 pages, 126 illustrations, some in colors, and a colored plate. Ophthalmology has two quite different meanings. It is the sum of our scientific knowledge of the eye and it is the art of relieving the morbid affections of this organ and its appendages. To the scientific end proper but 94 pages are devoted, exclusive of course of the dioptrics, etc. The pathology begins in the usual order of locality—conjunctiva, cornea, sclera, uvea, lens and vitreous. The second section deals with affections of the retina and optic nerve, the third with dioptrics, etc., and the fourth—very briefly—with intraocular pressure. The second part of the work deals with affections of the adnexa and the third with injuries. Special sections are devoted to general diagnosis and general treatment but these are brief, for the subjects are all given in appropriate connection under the various diseases.

EATING TO LIVE LONG. By WILLIAM HENRY PORTER, M.D. With Introduction by EDWIN F. BOWERS, M.D. Chicago: The Reilly & Lee Co., 1920.

DIETETICS is the most inexact of sciences, if we may judge from the contradictions which we find in the doctrines promulgated by the professors of it. As the author of this interesting book says in his preface: "One might rather expect that in the half million or more years in which human beings have been inhabiting this planet, they would have developed an ample and adequate understanding of the uses of food, or an instinctive if not an acquired knowledge of proper food selection. Such is not the case." And the trouble is that the preacher of every system—Haig, Kellogg, Porter, Salisbury, Christian—each and every one points to results to prove that he is right, and each and every one does really get results in many cases; he hears of these good results and records them with joy and ever-increasing confidence in his regimen; the failures do not report themselves but go off to try some other system or abandon all system. In this book Dr. Porter writes very pleasingly and plausibly in support of some novel dietetic views; the reader may not accept these views, but whether he does so or not he will be set to thinking—and the author who makes his readers think has done his work well and justified his undertaking.

ÉTUDE CRITIQUE DE L'ÊTIOLOGIE DES BRONCHITES CHRONIQUES AVEC SCLÉROSE PULMONAIRE. Par DOCTEUR JACQUES DALSACE. Paris: Félix Alcan, 1920.

THIS volume is a separate imprint of a Paris thesis. It is largely taken up with 18 case histories, which are followed by summaries of the symptomatology, the cyto-bacteriology, the investigation for syphilis and tuberculosis, the causal factors and the pleural complications. There is a two-page summary from which it appears that bronchiectasis is not at all considered, the picture consisting of chronic bronchitis, emphysema, and sputum which may or may not contain Koch's bacillus; to which is added a focus of pulmonary sclerosis, usually at the apex. This sclerosis plays a preponderant rôle in the genesis of the affection.

INGUINAL HERNIA, THE IMPERFECTLY DESCENDED TESTICLE AND VARICOCELE. By PHILIP TURNER, M.S., F.R.C.S., Assistant Surgeon, Guys Hospital. Pp. 104 with 22 illustrations. London: J. & A. Churchill; Philadelphia: P. Blakiston's Sons & Co, 1919.

WITH perhaps a few exceptions under special circumstances, Turner agrees with the hypothesis advanced by Russell of Melbourne, in 1899, that in all cases of inguinal hernia, both in children and in adults, the sac is always a congenital structure and is always derived from a persistent patent funicular process. This is generally known as "Saccular Theory." After discussing this at length, together with the anatomy of the parts and certain pathological considerations, Turner says: "The practical bearings of the saccular theory, and the considerations which arise from it on the operative treatment of hernia, may be summed up as follows: (1) The essential cause of inguinal hernia is the presence of the congenital sac. There is no primary weakness of the abdominal wall which causes the hernia to appear. (2) Hence, to cure the hernia, it is essential to completely remove the sac. As there is no primary weakness, there is no need to attempt to strengthen the inguinal canal. (3) The operation should be carried out as soon after the appearance of the hernia as possible, before the development of any secondary weakness. (4) In cases where there is advanced and irrecoverable secondary weakness the sac should be completely removed and an attempt made to strengthen the inguinal canal. (5) The operation should, in all cases, be carried out with the least possible damage to the structures entering into the formation of the inguinal canal. (6) The external abdominal ring, since it is an important insertion of the external oblique, should not be divided unless, for some reason, absolutely necessary for the satisfactory performance of the operation. Based on this conception of the conditions, Turner recommends an operation along lines first suggested by G. L. Chiene, and which differs in many respects from the Bassini and its more common modifications. The incision in the external oblique is not prolonged through the interlacing intercolumnar fibres which form the intercolumnar ligament binding together the pillars of the external ring at its apex, but stops about ½ inch short of the ring margin. By blunt dissection the aponeurosis is freed from underlying structures and the lower edge of the internal oblique is retracted upwards and inwards. The cremaster is torn through exposing the cord and sac just below the internal ring. The sac is separated and ligated very high up and the excess of sac cut away. The operation is then concluded by suture of the external oblique aponeurosis, sometimes with a stitch or two extra to narrow the external ring, and suture of the skin. In most cases he does not think that the customary suturing of the conjoined tendon to Poupart's ligament is either necessary or advisable; but he says it may easily be done through this exposure if there seems to be general weakness of the abdominal wall. We doubt if this method will meet with much favor in this country, where most of us, at least, suture the conjoined tendon to Pouparts ligament in children as well as in adults, even though we have various methods of imbricating, overlapping or doing plain sewing when it comes to the aponeurosis.

The chapters on imperfectly and abnormally descended testicles are interesting but there are much better methods of treatment than the possibly rather dangerous one suggested by the author. The author's operation for varicocele differs from the ordinary excision method only in minor details. Turner's book makes interesting reading but we doubt its having much influence in modifying the commonly accepted methods in operative technique.

EMOLISI URINARIA. Prof. ALFREDO AMATI. Napoli: G. Borelli e Figlio, 1919.

THIS brochure of 46 pages written by a docent of Semeiotic Medicine in the University of Naples has neither index nor table of contents. The sections of the text are devoted to osmonocivity, acidity—alkalinity, coloring matters and other substances concerned in hemolysis, with clinical cases and protocol of animal experiments. The conclusions reached are that physiologic urine has a constant uro-hemolytic coefficient, and that in nephritic subjects and subjects with malignant tumors this coefficient is notably and constantly altered.

IL MOVIMENTO DEMOGRAFICO A NAPOLI DURANTE LA GUERRA (1915-1918). Prof. GIUSEPPE CRISTALLI. Napoli: Officina Cromotipografica "Aldina," 1920.

THE author who is distinguished as on obstetrician has as *motifs* the lowered birth rate which must be restored to that of peace times, the problems which arise from sexual relations, the saving of infant life including the illegitimates and analogous subjects, including the increased mortality from tuberculosis. The volume is a small brochure of 47 pages presenting numerous tables of vital statistics, to which class of literature it belongs.

Society Reports.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

(From Our London Correspondent.)

THE eighty-eighth annual meeting of the British Association opened at Cardiff, Wales, on August 24 last, when Dr. W. A. Herdman, F.R.S., Professor of Oceanography in the University of Liverpool, gave his presidential address.

Oceanography.—The address was a remarkably lucid explanation of the scientific and practical aspects of oceanography and was in effect an urgent appeal to the inhabitants of the British Isles to become better informed in regard to their national sea fisheries and to take a more enlightened interest in the basal principles that underlie a rational regulation and exploitation of these important industries. Professor Herdman very rightly insisted on the point that national efficiency depends to a very great extent upon the degree in which scientific results and methods are appreciated by the people and scientific investigation is prompted by the Government and other administrative authorities. He emphasized the fact that the principles of science apply no less to aquiculture than to agriculture. To increase the harvest of the sea the fisheries must be continuously investigated, and such cultivation as is possible must be applied, and all this is clearly a natural application of the biological and hydrographical work now united under the science of oceanography.

Anoxemia.—Mr. J. BARCROFT of Cambridge, as president of the Physiological Section, offered a constructive criticism of the latest views enunciated by Dr. J. S. Haldane of Oxford on anoxemia or lack of oxygen in the blood. It must be borne in mind, he said, that this condition should be distinguished from excess of carbonic acid, the usual popular conception of lack of oxygen. The condition in its purest form is met with at high altitudes, where there is literally too little oxygen to breathe. It is also met with in cases of anemia, where the red corpuscles of the blood are deficient in number and so carry too little of the gas to the tissues of the body. And lastly it occurs when the blood does not circulate freely, as in various diseases. According to Dr. Haldane "Anoxemia not only stops the machine but wrecks the machinery." The president showed that the first part of this statement was absolutely correct. The second part, however, remained somewhat less certain. He enforced the point by examples telling how Dr. Haldane and Dr. Kellas spent an hour in a chamber in which the air had been reduced to a low pressure. Both these observers certainly became mentally affected. As Mr. Barcroft said. "Clearly each believed the other to be complete master of his own faculties, but it is evident that Dr. Haldane was not so. I gather that he has no recollection of what took place, that whenever he was consulted about the pressure he gave a stereotyped answer which was the same for all questions, that even with a little more oxygen present he was sufficiently himself to wish to investigate the color of his lips in the glass, but insufficiently himself to be conscious that he was looking into the back and not the front of the mirror. Dr. Kellas, who could make observations, never discovered Dr. Haldane's mental condition, though boxed up with him for an hour, and went on consulting him automatically. Yet the after-effects show that there was no destruction or "wrecking" of the brain in either case. The conclusion therefore is that "no degree of anoxemia which produces a less effect than that of complete unconsciousness leaves anything more than the most transient effects. The train of symptoms in anoxemia suggested alcoholic poisoning, if the condition was rather less acute, *i.e.*, more chronic, fatigue was simulated and irritability occurred. As Mr. Barcroft stated, "anyone who has experience of high altitudes knows to his cost that life does not run smoothly at 10,000 ft." Nevertheless, it was a fact that men lived and worked at high altitudes. Two reasons as to how this was accomplished had been advanced. First, more red blood corpuscles appeared in the blood, to carry more oxygen, and secondly, the lining membrane of the lung developed a power to "clutch at the oxygen" in the air and force it into the blood under pressure. In discussing these views the speaker pointed out that at high altitudes the blood may contain plenty of oxygen but does not contain it at the necessary pressure. In his words "the lowness of the pressure and not the deficiency in the quantity is the cause of the symptoms observed." He showed that an increase of red blood corpuscles could not give the needful increase of oxygen. He also criticised adversely the view of the Oxford School and notably that of Dr. Haldane, that the lining membrane of the lungs could act as described. He himself had lived for six days in a glass respiration chamber under reduced oxygen pressure in order to put this theory to a practical test. If the lungs were capable of acting as the Oxford School suggested his blood should have been oxygenated, that is, bright red. But if the Oxford School were mistaken, his blood would be dark—an artery was opened by a surgeon. The blood was dark. Mr. Barcroft contended that the sound method of dealing with anoxemia at high altitudes was "to give oxygen." This was being done in connection with aeronautics. It may be remembered that during the war, gas warfare brought fresh interest to bear on the study of gases of the human blood, and of oxygen in particular. In investigations in this direction Drs. Haldane and J. Barcroft were especially prominent.

The Usefulness of Anthropology.—Professor KARL PEARSON, President of the Anthropological Section, in his presidential address, laid stress on the need for rendering science (anthropology included) useful, and sketched the methods by which this object might be attained, so far as anthropology was concerned. He said in part: "I fear that 'the best is yet to be' cannot be said of our multitudinous observations on 'height-sitting' or on the censuses of eye or hair colors of our population. These things are dead almost from the day of their record. It is not only because the bulk of their recorders were untrained to observe and measure with scientific accuracy, it is not only because the records in nine out of ten cases omit the associated factors without which the record is valueless; it is because the progress of mankind in its present stage depends on characters wholly different from those which have so largely occupied the attention of the anthropologist. It is that, seizing the superficial and easy to observe, he has let slip the more subtle and elusive qualities on which progress, on which national fitness for this or that task, essentially depends. The pulse-tracing, the reaction-time, the mental age of the men under his control are far more important to the commanding officer, nay, I will add to the employer of labor, than any record of span, of head-measurement, or pigmentation categories. The psychophysical and psychophysiological characters are of far greater weight in the struggle of nations to-day than the superficial measurements of man's body. Physique in the fullest sense counts for something still, but it is physique as measured by health, not by stature or eye-color. But character, strength of will, mental quickness count for more, and if anthropometry is to be useful to the state it must turn from these rusty old weapons, these measurements of stature and records of eye-color, to more certain appreciations of bodily health and mental aptitude, to what we may term 'bigorimetry,' and to psychometry. It appears to me that if we are to place anthropology in its true position as the queen of the sciences, anthropologists must not cease: (1.) To insist that our recorded material shall be such that it is at present or likely to be in the near future, utile to the State, using the word 'State' in its amplest sense. (2.) To insist that there shall be institutes of anthropology, each with a full staff of qualified professors whose whole energy and time shall be devoted to the teaching of and research in anthropology, ethnology and pre-history. At least three of our chief universities should be provided with such institutes. (3.) To insist that our technique shall not consist in the mere statement of opinion on the facts observed, but shall follow, if possible, with greater insight, the methods which are coming into use in epidemiology and psychology.

Zoology.—Professor J. STANLEY GARDINER, president

of the Section of Zoology, dealt with the professional side of zoology and deprecated the fact that the subject was being broken up into small sections devoted to special economic objects, while at the same time sufficient trained zoologists could not be found for posts that were vacant. He said that during the war men were required who had passed the Honors Schools in Zoology, and hence were presumably capable of doing the work, to train for the diagnosis of protozoal disease. All names from 1905 to 1914 were asked for and the average number was under 14 per year from all English universities. In the year 1913-14 every student who had done his Honors Course in Zoology in 1913, could, if he had taken up entomology as his subject, have been absorbed into the economic applications of the subject. Trained men were needed to undertake scientific fishery investigations, and could not be found. Posts were advertized in animal breeding, in helminthology, and in protozoology, three other economic sides of the subject. The Natural History Museum wanted systematists and there were many advertisements for teachers. The speaker did not know how many of these posts were filled, but it was clear that not more than one-half, or even one-third, could have been filled efficiently. Could any zoologist say that all was well with his subject in the face of these deficiencies? He therefore urged that more attention should be paid to zoology as the science of living animals, and less to the bare facts of anatomy and classification.

In this connection reference may be made to the discussion on medical education at the recent meeting of th British Medical Association, when suggestions were made by many leading men of the medical profession as to lightening the medical curriculum. A tendency was displayed to shelve zoology, and in the discussion the other day following Dr. Gardiner's address, in which many well known zoologists took part, this tendency was commented upon as well as the action of the Board of Education in excluding zoology from curricula in favor of botany.

The Mendelian Theory.—MISS SAUNDERS, president of the Botanical Section, discussed the latest developments of the Mendelian theory, holding that the outlook was promising for proving many of the moot points, referring to the relative influences of genetic constitution and of the environment in shaping organisms, she drew attention to the fact that with regard to some characteristic the organism was a self-controlled independent system. In such cases the soma reflected under all observed conditions the genetic constitution expressed in the Mendelian formula. Knowing the constitution of the parents, the appearance of the offspring could be predicted accurately and no correction was required for the effect of conditions of temperature, humidity, illumination, and the like. Per contra, most somatic characters showed some degree of variability arising as the result of reaction to environmental conditions. The speaker emphasized the need for more organized co-operation in the experimental study of genetics. The attitude was not uncommon to regard the study of genetics as a science apart, but the complex nature of the problems required that the attacking force should be composite, representing all arms.

Mendelism and Darwinism.—Dr. BATHER, president of the Geological Section, considered the relation of Mendelism and fossils. The discussion which was joined in by the president of the association, by the presidents of Botany and Zoology and many other representatives of the three branches of science concerned, was summarized somewhat as follows: It may be premised that the discussion dealt with the mode of the process of evolution. No speaker doubted the fact of evolution, but it was apparent that unanimity has not yet been reached in this controversy. Darwin held the view that whatever might be the cause of evolution, it had come about by the summation of small modifications. Examination of every individual plant or animal showed the presence of minute differences from other animals and plants of the same kind and Dr. Bather thought that these were the chief material on which natural selection acted. There had always been a school which looked to occasional large variations called sports or mutations, as the more probable source of the new species, urging that as species were discontinuous, that is to say separated by gaps, it was more natural to assume that they had come into existence by the selection of discontinuous variations. This school was suddenly reinforced by the rediscovery of Mendel's work on hybrid peas, and his theory that organisms were compounded of unit factors and each of which was transmitted and inherited in a state of purity. An eager body of experimental workers followed the Mendelian line of investigation and added triumph after triumph to their experimental dissection of organisms into unit factors and their tracing of the fate of these factors in inheritance. Some of the more extreme partisans of the view discarded natural selection and the influence of environment from their conception of the process of evolution. They returned to a new form of a mystical medieval theory and held that evolution was simply a development of unit factors, all of which had been contained in the primordial germ of life. Mutations were inherited or transmitted in all their purity, but variations due to the environment left no trace on the permanent chain of life. Students of fossils might have been expected to support the view that evolution had come about by sudden changes, especially as the gaps in the series of fossils were great. But, on the other hand, they were unanimous as to the evidence from the rocks being in favor of slow, continuous change. Wherever a series was complete, and had been studied carefully, it showed a slow continuous evolution. It showed, moreover, that the points in which old animals differed from young animals, very frequently anticipated the changes by which newer or later species differed from older earlier species. The facts strongly supported the belief that somehow or other the environment had an effect on living creatures, and that the effect became grafted on the constitution of the race, so that it would subsequently appear independently of the environment. They believed, therefore, that evolution was continuous, that some force like natural selection directed it, and that the environment and not the unrolling of latent possibilities was the chief factor in eliciting variation. As was to be expected in the case of an extremely active branch of experimental science, the advocates of Mendelism were not all in agreement. But it was admitted by many that Mendelians had laid too much stress on discontinuity, and that what they called mutations and unit factors were often so minute that only experts could identify them. Still more important was the admission that the Mendelian theory of the purity of the unit factors could not be maintained. In certain cases Mendelian units were transmitted without alteration, while in a growing number of cases it appeared that blended inheritance was the rule. On the whole, the discussion tended to show that Mendelian work, instead of being opposed to Darwinian principles of evolution, was likely to reinforce them.

This discussion on Mendelism and Darwinism was the *pièce de resistance* of the meeting. The members of the British Association seem to take much delight in arguing as to whether Darwin's hypothesis that evolution may take place by the accumulation of small preferential differences still holds good, while the Mendelian members either put on one side Darwin's theory or endeavor to make it coincide with the principles enunciated by the wonderful priest. It may be remembered that when the British Association met in Australia six years ago Professor William Bateson, the leader of the British Mendelians, denied the validity of the Darwinian theory, remarking that we were indebted to Darwin for his matchless accumulation of facts, but that we could not follow him in his philosophic theory. Since that time arguments between the respective theorists have waxed hot and almost furious. Nothing was decided in this year's discussion. As said before, Darwin's position as a teacher was reaffirmed and the value of his ideas as a working hypothesis was substantiated by the majority of the speakers, who were probably Darwinians. But the hard and fast Mendelians will continue in their belief that changes in species, the birth of species, and possibly the decay of species, do not take place because environment changes the germ-plasm in the reproductive organs of animals, but arise from the germ-plasm itself.

The Mental Effects of Alcohol and Opium.—The work

in the Psychology Section was extremely interesting. One of the first papers read in this section was by Miss May Smith and Dr. W. McDougall, dealing with "The Mental Effects of Alcohol and Opium." In order to test the effects of alcohol, dotting machines were used for "attention" and lists of related words for "memory." It was found that the general effects of alcohol were to deteriorate these powers except under certain fatigue conditions, when alcohol improved both powers; opium, on the contrary, improved both powers, whether under normal or fatigue conditions. The fatigue was engendered by loss of sleep for three nights. The tests were made every day, and the growth of recovery traced. Precautions were taken with the drug experiments, so that the person subjected to the test did not know what drug was being taken. The results were not due, therefore, to suggestion. The more diluted the alcohol was, the weaker was the effect; and alcohol taken after a meal had a much less evident result than when taken four or five hours after a meal.

Dreams of Children.—At a joint meeting of the Education Section and the sub-section of Psychology, Sir Robert Blair presiding, Dr. C. W. Kimmins discussed "the dreams of children who are physically abnormal." He said in part that the great value of the dream of the neurotic in the diagnosis of cases of mental disturbances had been proved beyond all dispute in the treatment of war neurosis and a great variety of nervous ailments. On the other hand, the dream of the normal healthy child also appeared to him to open up a very useful field for research as being the best method of investigating the unconscious, which played such an important part in human behavior. Dealing with an investigation of the dreams of 500 physically defective, blind, and deaf children who were not suffering from mental defects, he said that the dreams of the physically defective differed from those of the normal in the following ways: (1) They dream far less about food, from which it would appear that the crippled child is better fed than the normal child. (2) Among the fears, a larger proportion dream of accidents, and the fear of animals is clearly greater than among normal children. (3) The kinesthetic (falling, flying, etc.) dreams are more common, especially at the ages of thirteen and fourteen years. (4) Among the fulfilled wishes, visits to the country bulk very largely. (5) The death element in the dream occurs more frequently than is the case in normal children, and more even than in the dreams of the deaf and blind. A curious feature of the dreams of physically defective children was that the dreamer was always a normal child. They even dreamt of acts of bravery and adventure. The dreams of deaf and blind children were clearly marked by special characteristics. Those of the deaf child were far more interesting and full of life. The content of the mind was much richer with its vast store of visual experiences, and there was a wealth of variety which was absent from the dreams of the blind. His investigation fully confirmed the results obtained by Jastrow and Heerman, viz.: (1) That a child who becomes blind before the age of five never sees in his dreams. (2) That when total blindness occurs between the ages of five and seven, much depends on the mental development of the child as to whether he sees in dreams in after life or not. The well developed child mentally certainly does; the evidence with regard to the others is not so clear. (3) That all deamers becoming blind after the age of seven see in dreams even after an interval of many years, and apparently with little diminution in clearness. Blind children under normal conditions dreamed far less often than deaf children; but this was not true at the time of the air raids. The air raids had comparatively little effect on the dreams of the deaf, but the influence of these on the blind was very marked, more so on this than on any other type of child. Long after air raids had ceased, the blind child dreamt of them, though there was practically no trace of them left in the dreams of the deaf. Bravery and adventure played an important part in the dreams of the deaf, especially in those of the girls, who, in their dreams, took an active part in the war, performing deeds of valor; but they had no place in the dreams of the blind. The fear of fire was very common in the dreams of these children. A study of the dreams of the deaf threw an interesting light on the much discussed question of the cause of the kinesthetic dream. As a result of the investigation, it appeared that this type of dream only rarely occurred before the child reached the age of ten, and that then a fair proportion of children's dreams were of this nature. The proportion steadily increased up to the age of seventeen. Further, any illness involving a high temperature tended to increase the number. In the dreams of children who had been deaf from birth, however, no falling element appeared. This fact supported the physiological theory as against the other suggested solutions of the question. Muscular memory played an important part in dreams. It was remarkable how little school activities apart from those involving muscular movements affected the dream; whereas, in blind children in whom reading was acquired by the sense of touch, the memory of stories formed a large proportion of the dream material. Dr. Kimmins was convinced that from an educational point of view there was in the dream a valuable and fascinating field for research, and that a further study of the dreams of children who were physically abnormal might clear the way to a fuller understanding of the significance of the dreams of normal children. A careful study of children's dreams might throw much light on the special interests and desires of the child at different ages, and especially where persistent dreams were recorded of unfulfilled wishes on those elements which were conspicuously lacking in the life of the child and which might seriously interfere with his natural development. From various sources there comes a large body of evidence as to the very great influence the unconscious exerted in every department of mental activity, and a fuller knowledge of the unconscious might be as essential in dealing with the normal development of children as in the abnormal cases, in which it had proved to be of such extraordinary value. If this were true, then the dream, as the best means of investigating the unconscious, must play a very important rôle in the educational developments of the future.

Relation of Physiology to Medicine.—In the Section of Physiology, Dr. T. Lewis, F. R. S., discussed this subject. He said in part that in dealing with the relations between the science of physiology which studied the normal functions of the animal body, and medicine which treated the human body in disease, he spoke primarily as a physician. Physiology, originally the offspring of medicine, had become to medicine in its old age a chief pillar of support. It was his personal conviction that human as opposed to animal physiology should form the central point of physiological teaching to medical men. To confine the physiological lessons to the human body was impossible, for by far the largest part of our knowledge of the functions of the human body was still derived analogically from observations of the lower animals. But knowledge that had been obtained, or was now obtainable by observation from man himself should be constantly stressed, and animal physiology should be taught where it supplemented knowledge so obtained. It was of considerably greater importance to the student of medicine that he should witness a normal phenomenon, or rather a given principle, by observation upon the human rather than upon the animal body. It was where it could not be displayed in man, or where it could not be displayed with the same fine degree of certainty, that animal physiology should be called in. There were several reasons why this should be the trend of modern physiological teaching to medical students. First and foremost, students in their most impressionable period would thus learn how to investigate the human body. In talking with physiologists he found not infrequently that they but dimly realized the difficulties of this task and failed fully to appreciate how enormous was that barrier between physicians and the working organs of man, namely, the unbroken skin. Yet that barrier must be and could be passed, for its passage was vital to the present and future success of medical science and practice. The problem of what was happening in the human body was infinitely harder to solve than that which asked what was happening in the animal body, for in the former case the methods of examining and observing were usually far more indirect. The student was taught to stimulate the vagus nerve in the frog and to note the effects. At the same time he should be taught to press upon the vagus in the carotid sheath

of his fellow-student and to observe the similar lapse of heart beats. Physiologists had to face the fact that the large majority of students who passed through their hands would encounter in their daily work problems far harder to solve than those which they themselves dealt with in their laboratories. He spoke from personal experience in saying that medical students, when they came to the teaching hospitals from the physiological laboratories, had not yet learned to handle a man, their senses of hearing and touch were not sufficiently developed, and yet they were to handle men for the rest of their days.

The Prevention of Myopia.—Dr. F. W. EDRIDGE-GREEN, taking as his subject the prevention of myopia, said in part that the direct exciting cause of myopia appeared to be increase of intraocular tension through back-pressure on the eye, therefore lengthening its anteroposterior diameter. There was no satisfactory evidence that the use of the eyes for near work either increased or caused myopia. In the prevention of myopia any cause which would increase the intraocular tension by obstructing the outflow should be avoided. All exercises in children which involved strain with the eyes pointing downward should be avoided. A typical example of this was the exercise in which a child moved itself up and down from the floor with the eyes pointing downward. Physical training was of great importance, and it would be noticed that the ordinary forms of exercise, cricket, football, golf, etc., did not cause myopia, whereas lifting heavy weights, dumbbells, wrestling, boxing, or riding a bicycle uphill in a stooping position did. It was, particularly in those who had sedentary occupations, and who were not in a fit physical condition, and had an hereditary tendency to myopia, these forms of exercises should be avoided. Exercises which were found to cause a feeling of pain or tension in the eyes or distension of the veins of the neck should be strictly forbidden to myopes. Reading in a recumbent position with the eyes pointing downward was not advisable.

Psychology in Relation to the Industries.—In the Section if Psychology a series of papers were read on psychological aspects of industrial life. Professor E. L. COLLIS, in a paper on "The Psychology of Industrial Convalescence," said that the nation had recognized the need for dealing with convalescing disabled soldiers. The most successful treatment had been found to be that with an occupational objective, the reason being that occupational therapy was practical and largely psychological. What was only just coming within the realms of national conscious thought was that for many years industry had been providing and was continuing to provide as many disabled persons as did the war. Experience with disabled soldiers had demonstrated how few disabilities were sufficiently serious to cast a worker upon the industrial dust-heap. To enable him to train himself to become a productive, wage earning citizen he needed guidance and help. Yet one of our judges had pointed to the lack of medical and orthopedic treatment for injured workmen and of provision for their occupational reeducation. The strain of industrial life in peace time was just as productive of neurasthenia—machine shock, if they choose so to term it—as the conditions of active military service. Industry could be made a unique therapeutic agent; what was required was a hair from the dog that did the biting. Industrial neurasthenia played an important part in every illness which befell a worker, whether due to accident or disease. Such a worker required confidence in the future to enable him to resist the onset of illness or to enable him to recover. This confidence could only be created by the master he served—industry. The size and complexity of industrial concerns made the duty of creating this confidence a matter to be delegated by the firm to a special branch of management containing within its personnel medical and social experts. Referring to particular types of cases, he suggested that a worker who was recovering from injury should have his convalescence facilitated by re-admission to work for part time under medical supervision. Then there was the case of the loss of a limb. Men crippled in the war were fitted with artificial limbs, taught to use them, and encouraged to learn a new occupation. He submitted that a moral obligation rested with industry to finance treatment on these lines. Industry ought to provide means for industrial convalescence. What might be hoped for was that the dominant industry of each district would be developed at each place rather than an effort to develop indiscriminately. Then convalescing skilled workers from one district could, if necessary, be transferred to their own special trade carried on in another.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Forty-second Annual Meeting, Held at Boston, Mass., May 27, 28, and 29, 1920.

THE PRESIDENT, DR. NORVAL H. PIERCE, OF CHICAGO, IN THE CHAIR.

Address of Welcome.—President A. LAWRENCE LOWELL of Harvard University delivered this address. Looking at American professional men and comparing them with men of the same class in Europe, one was brought to the conclusion that the American specialized more and specialized earlier than did the European. The men in other countries were supposed to know more along general lines, as well as the subject of particular study. This was due to delay in all subjects. It took men a longer time here to fit themselves for medicine than for other subjects, because the amount of material they had to command was very much greater. One looked forward to the time when a simplification would take place; when some particular form of information would make way for the advent of general principles that would simplify the processes of education and that would permit of the command of a larger variety of facts than could be available through isolated factors. Why was it that Americans entered professions, at a later age than men in any other countries in the world? They were delivered at college later than men in other countries, in the same stage of education. Secondary education was completed at a more advanced stage, and was considerably behind that of Europe. Men entered college at 18, and the amount of information they possessed could easily be attained at 16 years. Medical men always advised against pushing boys and girls as rapidly as they might be pushed; and the whole weight of the profession was on the side of the slowing down of education. Family, physicians were constantly saying, "Don't push your boy too hard." The speaker, however, believed it better to put the work a little above a boy's head and let him reach up to it. It was a fact that boys were learning to make boats at an age when their grandfathers were commanding ships that sailed round the world. The war had shown us that the boys could rise to anything that occasion required of them, and he believed that they were capable of commencing college life at sixteen. The mind was more active at twenty than at twenty-five. However, his purpose to-day was not to give views on problems of education, but to extend a very cordial welcome to Harvard University.

Presidential Address.—Dr. NORVAL H. PIERCE of Chicago, in this address, said the history of laryngology could be said to be bound up with that of the American Laryngological Association, despite the fact that the membership was a small one, and that the policy of exclusiveness had been rigidly maintained. Many regarded this association as a kind of aristocracy, but this did not mean that the members could be content with things as they were. The war had brought men face to face with reality and with demands for new endeavor, and unproductive effort would soon be swept aside. In the past there had existed among American young men a spirit of satisfaction with superficial knowledge; this was shown by the large number of American candidates who failed to pass for the Rhodes scholarship at Oxford. The American seemed to resent the demand for close and long-continued study. Examination of candidates for the Army Medical Corps for the department of laryngology, disclosed the same condition. A large proportion of young men who considered themselves laryngologists were totally unqualified. In the teaching institutions there was an appalling lack of enthusiasm on the part of young men for beginning at the bottom and thoroughly schooling themselves for diagnosis. Young men who pre-

sented themselves at clinics and asked to be instructed in laryngology often appeared to think the course consisted of three operations tonsillectomy, septum resection, and turbinectomy! Thus laryngology needed to be protected against itself, by widening the scope of those who practised it. This was to be done first by better education of specialists. The instruction and equipment in medical colleges was inadequate for this. Two or three years' special study was necessary for this work and the degree of M.S. or Ph.D. might properly be offered to encourage students to attempt the work. For those who had not the time or means to cover it, a shorter course, comprising fundamentals, might be given. Students entering upon the study of a specialty should have received the degree of M.D. from one of the Class "A" medical schools, and in addition should have a year's experience as interne or laboratory worker. A minimum of one year's study of otolaryngology would then be necessary to fit the candidate for practice. The year's program should include 4½ months of fundamental study and 7½ months of clinical study. Fundamental study (24 weeks full time) should include: (1) Advanced gross anatomy of the head and neck: (*a*) paranasal cavities; (*b*) epipharynx, mesopharynx, hypopharynx; (*c*) larynx and esophagus; (*d*) three divisions of the ear; (*e*) surgical relations of the temporal bone; (*f*) venous sinuses of the brain. (2) Advanced histology of the nose, throat, middle and internal ear. (3) Embryology of the nasal cavities and paranasal cavities; the pharynx; especially of the tonsil, epipharynx; and of the middle and internal ear. (4) Physiology of audition, olfaction and voice. (5) Physics of sound. (6) Neurology. (7) General pathology. Clinical study should include: (1) Special pathology of the nose, throat and ear, including bacteriology; (2) otoscopy, rhinoscopy, pharyngoscopy; (3) direct laryngoscopy and bronchoscopy, esophagoscopy and suspension laryngoscopy; (4) functional tests of the middle ear, cochlea and static apparatus; (5) clinical diagnosis; (6) treatment, local, general and surgical; (7) operations on the cadaver; (8) skiascopy; (9) relation of the ear, nose, and throat to (*a*) internal medicine, (*b*) neurology, (*c*) pediatrics, (*d*) industrial medicine, (*e*) public hygiene; (10) preparation of history and records. Assistance in the form of fellowships should be given to students preparing to undertake this course.

Retention Crypts in the Infratonsillar Nodules as Common and Extensive Harbors of Pathogenic Bacteria.—Dr. THOMAS R. FRENCH of Brooklyn said that little attention had been paid to the presence of chronic infectious material in the chains of infratonsillar or lingual lymph nodes. The tonsilloscope, however, had discovered that these structures, when associated with diseased tonsils, acted as pathogenic foci. They had been very briefly described in the text-books. The speaker had studied particularly the chains of nodules lying on the lateral walls of the pharynx and the base of the tongue, directly beneath the faucial tonsils. These often became the seat of chronic infection. He had hesitated at first in introducing operative procedures, on account of the underlying venous network of these structures. Operation, however, had disclosed the existence, under the nodes, of a smooth limiting mucous membrane, obviously a fibrous capsule. Examination of the enucleated structure revealed pus and débris. It was clear that such disordered tissue could not be left without danger to the system. The nodules were easily and safely enucleated from the throats of children. In adults, under tonsilloscopic examination, numerous small slits or pin points, flush with the surface on the nodules, were shown, with the aid of a thin bent probe, to be minute crypts containing necrotic material, with pathogenic bacteria. The nodules were not present in a state of health. They appeared in the form of foreign structures, set upon the submucosa like a plaster form upon a ceiling. The underlying capsules were a continuation of the tonsillar capsule. The size varied from one-eighth to three-eighths of an inch in children; in adults they increased progressively in size. In children the masses were smooth, round-topped, and firm; in adults they resembled irregular folded material placed on edge. The interspaces formed deep pockets. The lingual tonsil appeared enlarged far less frequently than the faucial tonsil. The surface of the nodule might contain anywhere from 25 to 100 or more openings or crypts, varying in depth; some were shallow, but some were deeply penetrating, and with small mouths, often practically sealing up necrotic material. Such crypts sometimes evacuated themselves from overdistention. Thus far the *Streptococcus hemolyticus*, *Streptococcus viridans*, and *Staphylococcus aureus* had been isolated from these crypts. The diagnosis was made by means of the tonsilloscope, and with the use of a tongue depressor specially designed by the writer to facilitate examinations. The key to operative measures lay in the use of a block moulded to fit over the angle and under the lower edge of the jaw, in such a way as to serve as a resisting wall for an undercutting scoop of the arc of the Sluder guillotine. With this resistance the enucleation of a pharyngeal nodule was quite simple. The technique of the procedure was given in detail. Disposal of lingual tonsils presented more difficulty, and the best method had yet to be evolved. These structures were so close to the orifice of the larynx as to present a particular problem. Hemorrhage from nearby large vessels was one danger, and the risk of edema of the larynx from septic obstruction was to be feared. A possible solution would be to shave the tops of the nodules, thus cutting away their crypts and freeing the necrotic material. At all events the nodular trunks and pharyngeal branches could be safely enucleated. The blood loss during these operations had been found to be negligible. Any hemorrhage had been so far arrested by pressure by stick-sponges and counter pressure outside under the angle of the jaw. The operations were performed under general anesthesia. Other methods, such as curettage, and emptying of the crypt contents, could be tried in selected cases, and in those patients who refused more radical operation.

Dr. D. BRYSON DELAVAN of New York said that Dr. French's presentation was not the result of cursory and superficial work, but was the outcome of much knowledge and of patient and laborious study. The more one studied along the lines Dr. French had pointed out, the more one was convinced of the folly of the ordinary ways of removing the tonsil. Where septic conditions were present and failed to disappear after tonsillectomy, and where the tonsil remnants were removed as Dr. French had advised and instructed, the results were most gratifying. He trusted that this contribution, which was epoch-making in its way, would be carefully studied. The experience of those who had already followed it would be a guide to others.

Dr. G. SLUDER of St. Louis said Dr. French had launched a perfectly new study, and he did not think many of them had followed these cases as he had followed them. Upon the introduction of the tonsilloscope, five or six years ago, Dr. Sluder had predicted that it had a future capable of great development. This work was the result of careful and painstaking investigation; few had been so industrious. The nodules of which Dr. French had spoken seemed to be in close proximity to the lingual mass and crossed over behind the lingual fossa. In five or ten years these masses filled up and practically reproduced the entire tonsil.

Dr. H. L. SWAIN of New Haven, Conn., considered it impossible to intelligently discuss such a brilliant piece of work as Dr. French had presented, especially as it was upon territory in which they had not made a special study, and so could not achieve an intelligent conception of it. It had been said that all the new work was being done by young men; but this wonderful piece of work had been done by one of the oldest members. This tissue was definitely encapsulated and mechanically loosened upon enucleation. He was a little in doubt as to the location of the nodes. It was not clear what the lateral column of the pharynx had to do with the situation, but one had to deal with a group of lymphoid tissue, with the lingual tonsil above and the faucial tonsil below. This was related to the amount of growth of the intermediate body. The tissue seemed to be identical with the tonsil and lingual tonsil. The lymphoid structure was, to all intents and purposes, the same as the tonsil, in its effects upon the system, and was able to poison the system, so that the importance of removal was equal in value to that of the full-sized tonsil in any other situation. He admired

the first man who had had the courage to go into this mass and excise it. All had had experience with hemorrhages from the lower pole of the tonsil, which was exactly the part into which he put his tonsillotome.

Dr. C. W. RICHARDSON of Washington, D. C., paid tribute to Dr. French, who had been a member of the Association 41 years. This new contribution had come not from the younger men, but from one of the older ones, who had set all the men thinking. He thanked Dr. French for what he had done for himself individually in making this presentation.

Dr. L. A. COFFIN of New York thought Dr. French was not showing so much how to grow old gracefully, as how to maintain youth.

Dr. FRENCH, closing, said he was very much gratified by this appreciation and endorsement. He would have to be very much older before he would even begin to feel old.

A Case of Multiple Strictures of the Esophagus, Cured After Repeated Dilatation with Graduated Bougies.—Dr. C. F. THEISEN of Albany, N. Y., reported this case. The patient, a woman of 51, had been in the habit of using smelling salts for headaches, and when lying down, on one occasion, had swallowed some of the strong ammonia. Later she developed an inability to swallow any but liquid food. When first seen she was emaciated and cachectic, giving the impression of malignancy. Examination of the esophagus with barium salt showed five distinct strictures, the upper one near the cricoid, being very tight. The esophagoscope, with a special bougie, was passed through the upper stricture, the patient allowed to rest, then again passed. Flexible bougies made of lead were employed, of 14 mm. diameter. After a few weeks' treatment the patient was able to swallow, and began to gain in weight. Time would be required to say whether the cure were permanent or not.

Report of a Case of Syphilis, Vincent's Angina, and Sarcoma of the Pharynx, one Condition Following the Other in the Order Named.—Dr. THEISEN also reported this case in which second case an unusual combination was present in a male patient, aged 38, with ulceration of both tonsils. The physician had said there was no syphilis, but the Wassermann gave a four plus. Iodides were pushed, but the ulceration extended and the curious characteristic odor of Vincent's angina was noted. Smears from throat swabs gave a diagnosis of Vincent's spirillum. The ulceration continued to spread, until in three months the mucous membrane of the tonsils, tongue and cheeks was destroyed. The edges of the ulceration showed nodular formation. On pathological section a diagnosis of round-celled sarcoma was obtained. Radium was ineffective.

Symposium on Radium. Dosage, Envelopes and Duration of Treatment.—Dr. WILLIAM DUANE said that in the study of the treatment of malignant disease by radium and radio-active substances, he had worked on the principles underlying the methods of treatment. The fundamental principle was destruction of the tumor cell by filling the tumor with radium. There was no evidence that radium could transform tumor cells into normal cells. Destruction of an army was in two ways: shooting the men: cutting off supplies. This was what radium must do. The primary principle of a radioactive substance appeared to be the ejection of atoms of electricity from the substance radiated. Redistribution of the atoms followed. Radium had an inhibitory influence on the reproductive powers of the tumor cell. This made it valuable in treating metastases. The tumor must be filled so that the cells would not subdivide. Normal cells were much less sensitive to radiation than were tumor cells. As a rule radium did not affect surrounding structures.

Factors Influencing the Quantitative Effects of Radiation.—Dr. WILLIAM T. BOVIE, Harvard University, said that radiotherapy was different from chemotherapy. Studies of radiotherapy, using photographic principles were made. The rays had a tendency to spread from their source, and the intensity of the rays varied as the square of the distance from the source. The rays that passed through tissue did not alter the tissue, only those that remained affected it. If the first layer of tissue absorbed fifty per cent. of the rays, the underlying layer would receive fifty per cent. less. The effect on embryonic cells was according to the rate of conductivity. Beeswax was used in experiments to replace tissue, and the nature of the burns was noted. Models of these burns were made, and the size of them noted in relation to the quantity of radiation that produced them, and the different applicators. Studies were also made of the action of silver on the gelatin plate. Light was absorbed by the silver particles, which impressed the image on the plate. The Germans and Austrians used a threshold exposure to measure the speed of the plate, but apart from the blackness of the plate there was a latent image, so that if a plate were once exposed, the image was there, though not visible. An arm exposed to radium did not show it but the effect was there, so that a physiological process must be involved. Another point was that the influence of temperature on radiumized tissue was marked. The studies on the rays included intensity; effect of the rays on the tissues when they were absorbed; the physiological processes. The radiographer who did not know the physiological processes was apt to think his patients had an idiosyncrasy.

Results of Treatment of Malignant Disease of the Upper Air Tract by Radiation.—Dr. D. CROSBY GREENE of Boston, Mass., made this presentation, dealing with two groups of cases,—malignant disease of the larynx and that of the upper jaw. The material was collected from the Huntington Memorial Hospital where the treatment was carried out. The results of treatment in 37 cases of laryngeal cancer and in 15 cases of growths on the upper jaw were given in detail. The conclusions as to treatment were: (1) That in malignant disease of the regions considered the chief value of radium lay in its supplementary, rather than primary value. It should not supplant operation. (2) That in cases of extensive extrinsic laryngeal carcinoma about the upper orifice, in which operation entailed excessive risk, benefit might be expected in a very few cases by radium alone. The method of insertion of seeds gave the best results. In early intrinsic carcinoma of the larynx, thyrotomy and excision was still the best method. Active radiation of the cartilaginous framework of the larynx was followed by destruction. In moderately advanced cases, however, radium could be used supplementally. (3) in most cases palliative results in the way of retardation of the growth and relief of pain might be expected by radium treatment in some form. (4) in advanced upper-jaw cases treatment by operation followed by radiation gave promising results.

Dr. C. G. COAKLEY of New York said that in the treatment of malignant disease by radium, one had to learn more of the technique to be employed than one now knew. Experimentally it should be put in where the surrounding structures could not be reached. Usually radium would retard the progress of the disease for a time. He thought it had been proved experimentally and clinically that while there was a partial destruction of the tissues of the pharynx and larynx and improvement of the patient, a rapid extension and increase of the growth was apt to occur suddenly such as took place in no other way. One point observed in radium treatment of the nose and nasopharynx was the extraordinary amount of pain and burning produced, which no medication would allay. He had had eleven cases of cancer of the larynx. One case, radiumized in November, 1913, was favorable, for such treatment, as the growth was limited to one-half of the cord The man was given an improperly screened dosage, and while the growth diminished, there was terrible destruction of tissue and the trachea was destroyed. Dr. Wood sectioned the cord. Not a trace of epithelioma was found, but there was a septic bronchopneumonia, due to absorption of toxic material. In another case, there was an epithelima involving the upper part of the larynx. A tracheotomy tube was kept in two weeks. When the tube was removed there was considerable granulation tissue that was radiumized. The man was going about now with his tracheotomy tube still in position. The granulation tissue was burned out by the radium. Surgery could be used in cases where radium failed. Five cases of fibroma of the nasopharynx did remarkably well. One case of epithelioma of the palate had a recurrence after eight months. A young woman whose constant asthma was caused by nasal polyps was

treated by radium, the asthma was relieved, and some months after it was found that the polyps had entirely disappeared. This might have been due to radium.

Dr. H. P. MOSHER of Boston had seen few cases of cancer of the larynx and pharynx but had had more experience with cancer of the upper jaw. Since the war he had seen several cases. Radium had raised hopes, and he hoped it would not destroy them. It should be of use in superficial growths and in growths that had been rendered superficial. Dr. Coakley's case was opened into the mouth. He was strongly against opening into the mouth.

Dr. HARRY BARNES of Boston had used radium with success as a postoperative measure after excision of the malignant growth. The tubes were placed in the cavity (35 to 40 millicuries) left in about two weeks. If used at once to kill off any cells which might have been transplanted by traumatism, this measure prevented metastases Of six carcinoma cases, three died, two were alive and well, three successful cases in all making about 50 per cent. of good results.

Dr. HARMON SMITH of New York said Dr. H. H. Janeway had sent him all his cases. He had seen five cases of carcinoma of the larynx in 18 months. They were all inoperable cases. The growth might have been inhibited but the patients went on to ultimate death. One patient with lymphosarcoma of the tonsil died of metastases in the chest and brain. One man with lymphosarcoma of the right tonsil had radium applied and he disappeared. That might be a favorable sign. Fibroid tumor of the nasopharynx was malignant unless controlled. Very rapid progress of a growth should be classified as malignant. In one boy of 16 the tumor recurred as fast as it was removed. He died of hemorrhage. In another case, a young man, the tumor was radiumized, but radium had no effect. Operation was done and the man got well. Another man was sent from Bogotá, to have radium applications. They must make good with radium or else must use it only to lessen the growth, or post-operatively to dissipate the growth.

Nasociliary Neuralgia.—Dr. GREENFIELD SLUDER of St. Louis, Mo., made this presentation. He said that pain in the eyes, brow, and root of the nose was frequent, and of various origins. Localization of the pain of the several origins by the patient was not precise. Pains of frontal, ethmoidal, or sphenoidal sinuses, or nasal (sphenopalatine, Meckel's ganglion), or supraorbital, or nasociliary nerve origin, might overlap in their sensations. This last pain was usually referred to the small district bounded by the supraciliary ridge above the supraorbital notch laterally, and the nasal bones below. Sometimes it extended to the tip of the nose; rarely it was referred to the eyes. Patients often complained that they could not wear glasses because of soreness of the nasal bones. Severe degrees, however, of whatever origin, might be referred beyond these limits. Pain of supraorbital neuralgia was more widespread. Pain of suppuration of the frontal or ethmoidal sinuses under pressure, was of long-known recognition. Pain of vacuum frontal sinus origin was described in 1900. Pain of nasal ganglion origin, referred to this district, was described in 1907; it was usually accompanied by other painful sensations. Pain of sphenoidal origin referred to this district, was described in 1912; it, too, was usually accompanied by other painful sensations. Pain of supraorbital systemic toxic neuralgia was of classical description. After describing the nervous anatomy of the parts he said that this showed that the nasociliary nerve was quite near the surface of the membrane, and was more superficial than the nasal ganglion and was more easily cocainized than the nasal ganglion. A small applicator with 20 per cent. solution sufficed. This was passed upward on the inside of the nose, being held forward in contact with the anterior limit of the nasal fossa until it reached the roof of the fossa. By this procedure it arrived automatically in the apex of the angle formed by the cribriform plate above and the anterior limit of the nasal fossa. At this point the nasociliary nerve entered the nasal fossa. When the pain in this region was of nasociliary origin such an application of cocaine would stop it in a few minutes. Should it be of the other origins mentioned above, it would not be influenced by such an application. The differential diagnosis would furthermore reveal a tender spot in the floor of the frontal sinus if it was a case of vacuum or purulent frontal sinus origin (Ewing's sign). The speaker's observation so far had been that nasociliary neuralgia had usually been a transitory phenomenon in the course of cases which had been under observation or treatment for something else. The nasociliary neuralgia would appear from time to time in the course of other clinical conditions, and was usually not obstinate. It would yield to cocainization and applications of dilute carbolic acid. Four times, however, he had seen it the only clinical phenomenon. Once he had injected the nerve trunk at its entrance into the nose, with relief to the patient. The technique was that first advocatd by Otto J. Stein in his alcohol injection treatment of hyperesthetic rhinitis. A straight needle was passed upward in the nose in the same way as the applicator for cocainization. A few drops of 95 per cent. alcohol with 5 per cent. phenol were instilled into the nerve trunk at its exit from the ethmoidal slit.

Dr. H. L. SWAIN of New Haven, Conn., said Dr. Sluder had gone to a refinement that others had not approached. He called attention to the sphenopalatine ganglion syndrome, and now he was teaching the nasociliary type, to be added to the neuralgias that had borne his name all over the world. Dr. Swain had had an interesting case of the Sluder syndrome, which he referred to Dr. Sluder, who said it was a remarkable case. The sign that most worried the patient, an elderly woman, was Ewing's sign, which was very marked. That was relieved by the application of cocaine to the sphenopalatine ganglion. The pain immediately left. The woman had no knowledge of the subject and the supposition was that if one could have maintained enough pressure, the pain could have been relieved. In this case the pain in the angle of the orbit was the troublesome feature. Several eye specialists had been consulted, but their treatment did not relieve the Ewing's sign. A single application to the sphenopalatine achieved the effect. Dr. Sluder had advised injections of phenol and alcohol; that might no doubt be a good thing, but one would rather see him do it first. One hoped that he would discover something less extreme. The application of a weak solution of nitrate of silver prolonged the benefit of the cocaine. One might get a severe reaction with carbolic and alcohol. On four different occasions this winter he had seen these nasal neuralgias and had put cocaine and adrenalin over the ganglion. If Dr. Sluder's new discovery would relieve pain in this area one should follow him up in his work.

Dr. HARMON SMITH of New York said Dr. Sluder's article had helped to sell the volume in which it was printed; there were requests for the volume containing "Sluder's Syndrome." He had seen one case in which there was no relief by cocainization of the sphenopalatine ganglion. Dr. Faulkner injected the ganglion without effect. The ganglion was later removed.

Dr. J. E. MACKENTY of New York said that Dr. Sluder had always explained what one had seen and did not understand. All had had this experience. He had had a patient with nasociliary neuralgia. There was considerable inflammatory tissue in this region, which he removed with the Sluder knives, thus relieving the condition. There was another type of case. The patient had a sense of pressure over the distribution of the nasal nerve, as if something were pressing inside of the nose. This caused a great deal of distress and did not yield to treatment. He would like to know if Dr. Sluder would include this in the nasociliary cases.

Dr. HANAU W. LOEB of St. Louis said the interesting part of this report was that it made it possible to differentiate this type of pain from other types of pain of nasal origin. One could see the logic of this work. Had Dr. Sluder met any cases with pain referred to this region, but with a distant point of origin?

Dr. NORVAL H. PIERCE of Chicago had had a patient, an Episcopalian minister, who was obliged to give up his work in the church on account of a phonetic spasm, which when the larynx contracted, made him go through all kinds of grotesque facial contortions. He was greatly depressed about his condition. His son brought him to the office because of pressure symptoms in the nose—a sensation as if the nose were clamped by very

tight pince-nez. Dr. Pierce used equal parts of cocaine and sugar of milk for blowing up the nose. The man began to talk in a perfectly natural manner, the facial spasm disappeared, and the voice became normal. That lasted while the effect of the cocaine lasted. After that, whenever he had to preach or talk he used a tablet of 50 per cent. cocaine and sugar of milk. This was done long before Dr. Sluder published his work. The case must have been one of reflex trouble from the nose. Two things were puzzling, however, one was that cocaine relieved the pain whether applied on the right or the left side; the second, that hypodermic injections of cocaine had precisely the same effect. In nervous conditions one could not eliminate the systemic effects of cocaine any more than one could eliminate the constitutional effects of morphine when injected. One would like to know whether the local effect of cocaine was what produces the relief.

Dr. JAMES E. LOGAN of Kansas City, Mo., said Dr. Sluder was always able to crystallize their experiences for them. Several cases were seen in the last few years which might be called vasomotor neuroses. Dr. Sluder was pointing out the way in which one could localize treatment and handle these cases more intelligently. Dr. Sajous had used cocaine on the turbinates in his study of the reflex neuroses of the nasal cavity, but Dr. Sluder had brought out more clearly the connections of the subject from the diagnostic and remedial standpoints.

Dr. SLUDER, in closing, said Dr. Swain's case was evidently a nasal ganglion neurosis, the type that could be exploded by a single touch. The patient was very neurotic. In such cases the injection should be carried out under nitrous oxide anesthesia and a small amount of cocaine applied to the nasal ganglion. The gas did not complicate the issue. When coming out of the gas the patients were analgesic and responded readily to suggestion. Care must be taken in directing the needle. One must be on guard for the sphenoidal sinus. The middle turbinate made one think that one had transfixed the anterior process of the sphenopaxillary process. One might strike the pterygoid and then the injection was in the nasal fossa and a drop of alcohol ran down the throat. This was difficult to control under general anesthesia. Methylene blue with the alcohol facilitated matters as the blue solution was easily seen running down. A straight needle was better than a curved one, which was apt to catch.

Dr. HARMON SMITH of New York said the case mentioned by him had been operated on for maxillary sinusitis and had continued to suffer from neuralgia. Cocaine did not do any good. Dr. Sluder advised against continuing.

Dr. SLUDER said such cases transcended all categories for difficulty. The nerve supply of the nasal ganglion might come through the sphenoid fossa. In Dr. Smith's case a gasserian ganglionectomy was done. If one removed the entire sensory supply it made a cure in some cases but not all. The question was what is the source of the pain? Probably pain was transmitted by the sympathetic fibres that run in through the nose. However, masters of the study of the sympathetic, had declared that the sympathetic was purely a motor system, containing no fibres of a sensory nature at all. There was considerable literature, however, on the other hand to prove that the sympathetic had a sensory mechanism, that there existed a motor and a sensory supply, taking in the spinal ganglion. All cases of facial trigeminal neuralgia were not relieved by semilunar ganglionectomy. Cushing considered all this work a mistake. Many patients complained of inability to wear glasses because they hurt. Dr. Loeb had spoken of the orbital pain—Ewing's sign. The floor of the sinus was very thin. Other types of pain were associated with toxic origin or systemic disturbance. The nerve of the notch was extremely sensitive, and in these cases Ewing's sign was absent and the floor of the sinus was most tender. In the ganglion cases the nerve was more sensitive. Pain of the sphenoid might be the result of the trigeminus. Dr. Pierce's case was very interesting and raised the question as to how much of this effect was referred to absorption and systemic influence. In the beginning of this work in 1903 many of these patients were put to the test. An ignorant patient would tell one unmistakably what was the matter. He suffered and one could see by his expression that he was in pain. Cocaine was put in one the lower turbinates. One need not ask questions; if he were better he would say so. If he did not get better one could put in cocaine on the middle turbinate. If that helped he would say so. Then one could take the nasal ganglion. The statement of relief of pain would finally settle the question. If he were relieved, the diagnosis was made. The man begun to smile and say he felt better. The question of separation of local from constituional effect was not decided. Next time he got a case he was going to give a subcutaneous injection of cocaine to see if Dr. Pierce's point could be proved. In regard to Dr. Logan's question as to vasomotor neuroses in the nose, these were controlled by nasal ganglion injections. He had injected in the edema of hay fever when the whole nose was occluded, and this was cleared up by injection. Some of these results were very good.

An Unusual Type of Nasal Tuberculosis.—Dr. GEORGE E. SHAMBAUGH of Chicago presented this topic. Tuberculosis of the nasal cavities was rather a rare condition. Two forms were known: the hyperplastic or tuberculoma, and the ulcertaive, with tissue destruction. The two were often combined. In the case reported miliary tuberculous nodules involved the nasal mucous membrane, not associated with general miliary tuberculosis. The patient, a man of 43, of strong robust build, was seen first sixteen years before, he complained of nasal symptoms accompanied with marked enlargement of the cervical lymphatics on the left side. He had annoying dryness and burning in the nose and pharynx, chiefly on the left side, and he had left-sided frontal headaches, usually lasting two or three days. There was a daily rise of temperature to about 101 degrees F. General examination disclosed the fact that the cervical lymphatics were enlarged and tender; the axillary and inguinal lymphatics were palpable but not tender, and there was a nodule in the epididymis on the left side, probably tuberculous in origin. Examination of the nose showed congested membrane, with dry, glazed appearance, and atrophy of the turbinates. The septum presented an unusual appearance, being deeply congested and studded with many discrete, pin-head nodules, greyish in color. There was no tonsillitis. A nodule from the septum was sectioned and found to be of typical tuberculous appearance, but no bacilli were found. The clavicular gland was removed and found to be the seat of a chronic tubercular process, and a few bacilli were found. The patient was sent to Colorado for two years, and put on tuberculosis regime, during which time the cervical and nasal condition practically disappeared, and he had continued in good health since. It would appear possible that the nasal infection was secondary to a tuberculous focus in the epididymis, and that the process had travelled thence to the cervical glands. The nasal tuberculosis was in no way secondary to any pulmonary involvement.

Esophagism and Allied Disorders.—Dr. THOMAS HUBBARD of Toledo, O., said the pharyngeal plexus was concerned with a primitive function of such vital importance, that even slight disturbance might provoke psychic interference with resulting confusion of automatic reflexes. Thus chronic spasmogenic phenomena, esophagismus and cardiospasm, might be primary manifestations of irregular or reversed peristalsis. In this connection the hysterical throat was a manifestation of paresthesia and incoordinated muscle action, with psychic fixation in neuropathic individuals. It could be considered probable that disease conditions and local irritations of the gastrointestinal tract might initiate the reverse peristalsis, involving the esophagus. Abnormal reflexes and sensations could be referred to the beginning of the vegetative tract,—the region of the pharyngeal plexus. It had been found that through intimate anatomical association, the throat and larynx participated in the clinical syndrome, thus explaining the gastric factor in asthma. It should be remembered that the more peristalsis was emphasized as a factor in digestion, the more important it became to properly interpret abnormal peristalsis as a factor in disease.

Dr. B. R. SHURLEY, Detroit, Mich., said that under older procedures one was comparatively limited in the means of helping the large number of individuals who exhibited the various phenomena of a hysterical condi-

tion of the esophagus. These neuropathic and psychopathic conditions could be relieved with the same certainty that one relieves hysterical aphonia in laryngeal cases. One saw a number of cases in this rapid, nervous age. They could be watched through the fluoroscope and the spasm seen. Dilatation caused great relief. Triple bromides three or four times a day would help. These cases represented instability and short circuiting of the nervous system, of the vasomotor type. Many nervous women exhibited these phenomena. Reestablishment of the nerve tone by hypodermic injections of glycerophosphates and dilatation of the esophagus were beneficial. He had had one patient who was unable to eat when anyone was looking, and another who could only eat standing up. This was due to a fixed psychic idea. Later these same patients were eating ham sandwiches and peanuts and other foods which they declared they could not eat. These cases required special differential diagnosis. The personality of the patient and that of the physician counted for a great deal in the cure of these cases.

Dr. L. A. COFFIN of New York City, said if he understood aright Dr. Hubbard, he said that the chemistry of digestion was considered nowadays less than was the peristalsis. He would take issue with that statement on account of the present-day methods of the gastroenterologists. How much reverse peristalsis there was he did not know. For instance, in belching of gas, he had thought of it as gas expansion. Some years ago he had read a paper before the Trilogical Society dealing with the different forms of pharyngitis caused by marked gastric indigestion. He spoke of hypertrophy of the posterior tips of the turbinates as illustrative cases. He thought it might even account for the growth of adenoids. These granular pharyngitis cases were most amenable to treatment. He was speaking of gastric indigestion. The intestinal form was another matter, although one could also get reverse peristalsis from the bowel. One case was recalled of a man who came from the South and whose wife complained of his foul breath. The antrum was all right. An intestinal examination was made and the man was found to have a 5 + indol. He was cleaned up and the breath cleared up absolutely. He had had a regular fecal breath; but whether that was explained by reverse peristalsis one could not say. With intestinal putrefaction one got other disturbances, filled up nose, hay fever, ethmoiditis. One should not think of treating hay fever with the best vaccines made unless one first cleaned up the bowel. No class of patients gave such splendid results as did those patients in whom one treated the nose through the rectum,—from above downwards. The general practitioner sent cases all the time for laryngeal treatment, but if he had taken proper care of them they would not have come to the laryngologist. In one hospital with which he was connected a chair had been founded in the eye, ear and nose department for the treatment of the gastrointestinal tract. No operation was permitted and there was nothing but treatment of the gastrointestinal tract. There was no more satisfactory therapy in the clinic.

Dr. H. L. SWAIN of New Haven, Conn., was immensely interested yesterday by the esophageal exhibit by Dr. Mosher. He noted that the lobe of the liver was very near the lower pole of the esophagus. Supposing the lower lobe of the liver impinged on the lower end of the esophagus, a marked effect might be produced, both mechanical and obstructive. It certainly might induce contraction. Whether one had a history of reverse peristalsis or not, one had to cure these cases.

Dr. H. L. LYNAH of New York said that if one swallowed air one had to get rid of it. These neurotic cases suffer from that. In the bismuth meal one could see the reverse peristalsis of air bubbling through, although the meal was going down. A great many cases of malignant disease of the esophagus were labelled hysteria and they were discovered only after death. These functional spasms become organic sooner or later. One could use a small esophagoscope in these cases. Esophagoscopy without anesthesia was the surest cure in cases in which the patient thought he could not eat certain foods.

Dr. HUBBARD, in closing, said, in answer to Dr. Shurley, that he did not talk about treatment except by suggestion, through study of the etiology. The subject of cardiospasm, for instance, would take up a whole paper. There was no disease more difficult to cure than cardiospasm. Many cases died labelled organic stricture, that were purely cardiospasm. The autopsy showed no lesion. In these cases the psychic factor was not the important one. Just what made the formation of the sacculation was not determined. In regard to Dr. Coffin's remark as to the chemistry of digestion, the fact that one could remove large portions of the gastrointestinal tract without interfering with digestion showed that the chemistry of digestion had immense reserves. Peristalsis was more likely to be the cause of indigestion. Belchers were nearly always air swallowers. The actual volume of gas was not very great. Dr. Coffin labeled his cases granular pharyngitis, but that was wrong. All pharyngitis was caused by chemical irritation and autointoxication, perhaps due to retarded peristalsis. Chemical digestion took place in the gastrointestinal tract and disturbance of rythm upset the whole process. Organic disease was the cause of spasm. That was important and one should be warned. One could have small tumors in the esophagus which tended to produce esophagismus. He had had one such case, in a man who could swallow only liquids. A small pendulous tumor was discovered, just below the cricoid. The mass was not malignant and the next step would seem to be to snare it off. The paper was intended to account for certain obscure throat conditions, and also to develop a good working theory. Since he had had this idea in mind, the importance of reverse peristalsis as a cause of obscure throat lesions had been apparent.

Intrinsic Carcinoma of the Larynx With a Second Report of Cases Operated on by Suspension and Dissection.—Dr. R. C. LYNCH of New Orleans, presented this communication. Cases suitable for this procedure should be carefully selected; cases in which the growth involved the cricoarytenoid joint, the arytenoepiglottic fold, or the cricothyroid membrane were considered unsuitable. The procedure cited had for its basis a careful diagnosis, eliminating all other lesions by clinical and laboratory aids, excluding syphilis and tuberculosis, and taking careful pathological data of the tumor mass as excised. Under suspension it had been found possible to make out definitely the area of involvement and to cut sufficiently wide to insure its complete removal. Essential points for the operation were: (1) consent of the patient to do anything or all things necessary to save life and preserve natural respiration; (2) in intrinsic dissection, once the forceps take hold of the mass, they should not let go, thus avoiding transplantation of malignant cells; (3) the tumor should be circumscribed as far as possible and delivered on a cartilaginous plate, the cutting instruments not being permitted to come in contact again with the tumor mass; (4) the saving of tissue for functional use should not interfere with necessary complete removal; (5) all raw surfaces should be sealed with the actual cautery, thus closing the lymphatic outlet from the raw surface, and killing any transplanted cancer cells. The advantages of the operation were that it could be done quickly and without external incision, it was carried on within a closed box, offering the best resistance against matastases; the normal breathway was not interfered with, and there was more likelihood of nature establishing a cord for restoration of voice function. The cases operated on were nine in all. One died of recurrence. Two others had recurrence and subsequent laryngectomies and were now well. The other six remained well, during periods from six months to six years after operation.

Dr. D. CROSBY GREENE of Boston said Dr. Lynch had accomplished by his wonderful technique very much what those who had had experience with thyrotomy had done by the external route. There was no quarrel with anyone who removed cancer, provided the whole mass were removed. He had used the suspension apparatus from outside. In thyrotomy, where the region of the anterior commissure was involved, the patient must be well under the anesthetic, and the larynx must be cocainized and adrenalized. Thyrotomy was then done with an observer at the upper end to see if the knife was wide of the tumor while the suspension was being made.

Dr. J. E. MACKENTY of New York was very much interested in this wonderful presentation. Dr. Lynch had had nine cases with eight recoveries, which was better than the results with the external method. In New York cases very rarely came in in the early stages; 75 per cent. of the cases he had seen last year were inoperable. He had done three thyrotomies; otherwise, he did a total laryngectomy. He believed that Dr. Lynch's procedure was available in his hands, but he was very expert with his instruments; one would not consider it a safe procedure for the average technician. Dr. Mackenty did not believe he could carry it out with such success as thyrotomy. Another point was leaving the cartilaginous wall of the larynx. It left an indurated mass which would granulate and give trouble. Removal of the laryngeal wall with the cancer mass was of advantage in the technic of this operation.

Dr. LYNCH said he removed the perichondrium, but not the cartilage.

Dr. MACKENTY believed that it was disadvantageous to leave the cartilage there, with such a poor blood supply. He used the suspension a great deal, but it was difficult to judge of the extension of the cancer of the larynx, looking down upon it in that direction. He was often surprised on opening the larynx to see the extent of the disease. He was averse to removing tissue for examination, as it disseminated morbid cells.

Lung Mapping by the Injection of Bismuth Mixtures in the Living.—Dr. HENRY L. LYNAH of New York presented lantern slides illustrating his technique of outlining the bronchial tree and lung by means of bismuth insufflation.

Dr. T. HUBBARD of Toledo, O., said Dr. Lynah had mentioned accidental aspiration in pneumonia. Dr. Hubbard had one experience of accidental aspiration of bismuth, which made a diagnosis. The man, who was thought to be a globus case, was given bismuth. The apparatus was not working well and it was necessary to wait for another operator. The later examination discovered the fact that instead of being esophageal spasm it was esophageal paralysis. The bismuth had gone into the lung without causing a cough. The man was fed through a tube and recovered fairly well, and later developed general paresis, of which the esophageal paralysis was the first sign. Dr. Lynah's technique was perfectly marvellous and the possibilities were immense. Besides the diagnositic value, bismuth had certain healing properties. Injection in cavities was a therapeutic aid. Dr. Lynah, in closing, said the cases had improved before the bismuth was injjected. They could be got well if they could be kept long enough out of the hands of the thoracic surgeon. The bismuth was injected for only experimental and not for curative purposes.

Some Indications for Operation on the Nasal Sinuses in Children.—Dr. L. W. DEAN of Iowa City, Iowa, presented this paper. Operations on the nasal sinuses in children were not often indicated, as acute infections of these cavities tended to disappear spontaneously. Cases classed as chronic empyema yielded more readily in children than in adults. During three years routine examinations had been made of the nasal sinuses in 1,108 infants and children under 14 years, and in a large number of cases chronic empyema had been diagnosed. Most of these had been cured by the removal of diseased tonsils and adenoids. Hemolytic streptococcic infections, while resistant, could be treated without operation. Atrophic rhinitis and syphilitic cases were improved by simple ventilation and drainage, with local and general treatment. Extensive operations were rarely indicated, unless called for to remove immediately a source of infection. The pathology and systemic complications were factors in determining the need for operative procedures, but the size of the sinuses was an important factor. The *x*-ray was inaccurate in regard to the latter point. In operating upon the nasal accessory sinuses in young children it should be borne in mind that destruction of the bones of the face might have a deleterious effect in development, that the functions of the nose were important, and that injury should be avoided. Several cases of infection of the nasal sinuses in children, associated with multiple arthritis, were given in detail. These cases had required many months of study and treatment. With a large number of cases referred to the laryngological department it had been necessary to operate the sinusus in few instances. The hemolytic streptococcus disease of the sinuses was most difficult to eradicate. The only satisfactory way to treat the cases was by having them in the wards for as long a time as necessary—from six to nine months—in order to get results. Operations on the nasal sinuses to remove infective foci, where necessary, had been attended with good results. The patients, though cripples, were well-nourished and happy, and enjoyed play. With proper education they would be self-supporting. Their gratitude was compensation in itself for the time and care spent on their cases.

Dr. B. A. RANDALL of Philadelphia had had 35 years' duty at the children's hospital and had seen many cases of diseased sinus. In extreme cases he had had to resort to a crude, or perhaps brutal form of procedure to get drainage. Alligator forceps were put into the sphenoid and opened drainage through the front wall, thus securing drainage of the sphenoid. The ethmoid was different.

Dr. C. W. RICHARDSON of Washington, D. C., thought Dr. Dean and Dr. Coffin deserved great credit. Sometimes one did not differentiate these cases. A child came to him in April with a well formed mastoid in the right ear and abscess in the left ear. He incised the abscess and went away expecting to operate when he came back. On his return the child had marked exophthalmos of the left eye. The mastoid had cleared up without operation, the left ear was well. The exophthalmos was greater and the child appeared very ill, so that he saw the symptoms were related to the exophthalmos. The child was heavy, disinclined to play. He could not find evidence of sinus infection. The child went to the ophthalmologist and was kept two or three weeks, but nothing was done. The exophthalmos was so intense that the lids could not be closed. *X*-ray examination showed possible infection of the ethmoid cells. The blood count was 68,000 white blood cells, and increased polynuclears; temperature not above 99°. The eye man said he would open up the orbit, so Dr. Richardson planned to clean up the ethmoid cells, but found nothing, not even granulations. Then he thought of thrombosis of the cavernous sinus. The next blood count was 78,000 white blood cells. The pathologist said that it looked like leucemia. The child was taken to the most proficient *x*-ray man he could find, who made the diagnosis of suppuration of the ethmoid and sphenoid. However, the exophthalmos became so intense that they were convinced that it was orbital leucemia. There were no other enlarged glands anywhere, but the child had very large tonsils and adenoids.

Dr. HENRY L. SWAIN of New Haven, Conn., had been confronted with exophthalmos associated with orbital abscess, and had been tempted to do destructive work, which one should not do. In one case infection was caused by a single tooth, the only remaining one, and the infection passed up the ramus of the jaw, out by the pterygoid fossa and pterygomaxillary fossa, and into the orbit. There was no pus in the orbit, simply a great swelling. He had never heard of leucemia of the orbit, and was absolutely ignorant of that condition. There was a purulent infection with edema and swelling and the exophthalmos stretched the nerve, making it amaurotic for all time. In the case he had spoken of, he did not enter the sinus, it would have done harm. He made an incision in the jaw.

Dr. HARRIS P. MOSHER of Boston had been uncomfortable since Dr. Dean had read his first paper, thinking that there were things that he had been missing. He was in the same position as Dr. Skillern; he felt that one had not always found these cases and that one was not allowed to treat them for the necessary length of time—eight or nine months. How did one wash out the ethmoid in a child? In antra he had seen they were referred from the eye side and presented fistulæ below the eye, and were operated on through the anterior wall. How did one find the sphenoid in a child?

Dr. J. H. BRYAN of Washington, D. C., said the question of sinus involvement was very interesting and important. We all had met these cases to a greater or less degree. Dr. Dean's experience had been more decided as far as operation was concerned. One saw

cases that had constant involvement of the sphenoid at the expense of the other sinuses. Dr. Robertson, in the A. E. F., and at Walter Reed General Hospital, had found that the sphenoid was more frequently involved. The size of the sphenoid was almost constant. These were desperate operations, but nevertheless they were justified. Many thought that because a child was young no radical measures should be done.

Dr. J. E. LOGAN of Kansas City, Mo., said one should be grateful for Dr. Dean's work on sinus conditions. He would like to know if Dr. Dean had ever used autogenous vaccine before or after operating in the hemolyticus cases. This had proved a very potent factor in clearing up the case before operation. He had used it as a regular procedure.

Dr. GREENFIELD SLUDER of St. Louis, Mo., said a debt of gratitude was due Dr. Dean for his work on the sinuses in children. This question had been raised at the meeting of the American Medical Association three years ago. Now Dr. Dean had advanced knowledge and cleared up another difficult problem. He had said he did not operate quickly or lightly on the bones of children, and the speaker was glad to hear that statement, as he had had the same feeling for many years. One might conclude that no matter how much bone one took out of a child's nose, the activity of the bone cells was such that in three months time the bone would be replaced. One took desperate chances in bone removal in children. He had had a case in a child of orbital phlegmon from the paranasal walls. The only satisfactory drainage of the orbit was by the route of infection, that was through the nose. Drainage into the tranverse meridian was very difficult and complicated. He had operated on the middle turbinate with a small-handled knife and cut through the capsule to the ethmoid quickly. Three months later the orbital phlegmons recovered, the drainage was instituted, and the bone resumed the convolutions of the middle turbinate. One should not operate on the paranasal sinus in children except in conditions of dire distress. Dr. Dean's failure in the first case was not due to faults in his technique, but to rapid reproduction of bony growth on the part of the child. Sphenoidal headaches in childhood presented a difficult question. There were no nasal suppurations. Hyperplastic sphenoid without pus was difficult to diagnose because of the difficulty of the post nasal image. In such cases one should avoid operation and secure results by the sedulous pursuit of the lesion for treatment and not for surgery. Dr. Dean had called attention to the size of the sphenoid in childhood. W. B. Davis, in his monograph on the sinuses, had described a most ingenious device by which he removed the face and patched it up so that at autopsy it was hardly visible. He secured material from the early days of infancy, had followed back to the sixtieth day of fetal life, and had proved that sphenoid development began at that time; at two years it had progressed as far as the foramen rotundum and at five years to the meeting of the vidian canal. One could consider it as a sinus to be dealt with at that age.

Dr. CLEMENT THIESEN of Albany, N. Y., asked about another class of cases that had puzzled him very much, in children from five to fourteen years—a vasomotor rhinitis, with profuse discharge and supraorbital headache, with no pus, and with no evidence of sinus involvement by the *x*-ray.

Dr. J. E. MACKENTY of New York had derived much inspiration from Dr. Dean's paper. They were very much at sea on this question and needed light thrown on it. They had many facts in mind, but they were uncorrelated. In adults one could trace back the beginning of the trouble to childhood. They were persistent cases and most difficult to treat. These were the pain cases Dr. Sluder has described. The sinus trouble of childhood left the individual more or less crippled. As regards the bacteriology in these cases, the *Streptococcus hemolyticus* was one of the most difficult organisms to deal with and to eradicate. In the long chronic cases the *Staphylococcus aureus* was the most common germ. The sphenoid sinus was the most difficult sinus to treat; all the others simple, compared with the sphenoid. Bone, in these chronic cases, would tend to reproduce as fast as one could remove it. He had seen ocular trouble with children and had had three cases of retrobulbar neuritis that had to be operated upon. There was no profuse nasal discharge, but some change of coloring of the mucous membrane on the side affected. He had operated on suspicion; in one case vision was restored to a great extent. He would be glad to hear a word upon the treatment of chronic sinusitis; children were apt to have sinusitis all winter which would clear up in the summer. He had used suction and had had some success with autogenous vaccine. The child could be trained to use the suction apparatus at home. Used with the nasal douche the water was dragged through the nose. The question to settle was how much one was justified in operating on the sinus in children; how far might one dare to go in a given case.

Dr. B. R. SHURLEY of Detroit had found in these cases that a daily douche of bismuth and lime water, with suction and negative pressure, cleared up the sepsis very quickly. Dr. Dean had given them a new line of thought that ought to interest pediatrists and orthopedic men, who saw these cases first.

Dr. SLUDER wanted to know how Dr. Dean reached his diagnosis. Dr. Mackenty had said he operated on suspicion; he noted a change of color of the membrane; that was not suspicion; that was the diagnostic lesion. If one noticed that sign one would save many more eyes.

Dr. HARRIS P. MOSHER of Boston maintained that Dr. Sluder's pathology was suspicious. It seemed to be a question of color entirely.

Dr. SLUDER said he would let future generations decide that point.

Dr. DEAN in closing, expressed his appreciation of the discussion and emphasized a few points. These were the only four cases he had operated on in children. A child of five was the youngest had had seen with an operative sphenoid. He was glad Dr. Sluder had mentioned the reproduction of bone. He had noted it at autopsy. As to diagnosis, he thought careful daily study of the case, using the nasopharyngoscope, was of most value. They had also put the trocar into the sinus and cultured the contents. They used the long German silver cannula for the sphenoid. They surrounded the sphenoid with methylene blue, but got none back by this procedure. He had prepared a paper on the treatment of chronic empyema in children and would be glad to present it. Dr. Thiesan had asked about vasomotor rhinitis; the cases they had studied had been in children under twelve years. The antrum was washed out for diagnostic purposes. In one case of trophoneurosis, in a boy of two years, the antrum of Highmore was washed out and thick white pus was found. This was interesting to the pediatric men, as the cause of the disease was not understood. They did the puncture of the antrum in young children, with the *x*-ray plate in front of them. The floor of the antrum of Highmore did not extend below the inferior turbinate in the infant, but if one watched the plate one could get through the sinus and aspirate the antrum.

A New or Hitherto Undescribed Form of Maxillary Sinusitis.—R. H. SKILLERN of Philadelphia presented this case report. After a severe cold, the patient, Miss P., aged 50, had experienced a hemorrhagic discharge from the nose. This had become thicker and heavier, and had assumed the form of small pieces of liver, expectorated with great frequency, and always via the post nasal passage. Examination showed little that suggested sinus involvement, and the teeth were negative. Needle puncture of the left antrum, however, withdrew an ounce of pure unclotted blood. The cavity was irrigated and afterwards 50 per cent. alcohol with 1/2000 bichloride solution was injected. The blood withdrawn showed abundant hemolytic streptococci. The irrigations were continued, and the discharge became purulent instead of hemorrhagic. The alcohol injections were increased in strength. An abscess developed on the septum, which was incised, and a few days later a bloody discharge came from the right side of the nose, and the right antrum became filled with bloody fluid. Both antra were now irrigated and the secretion became diminished and milky in character. Triweekly irrigations were continued, but the disease became stationary. If untreated, it reverts to the hemorrhagic form. The exact status of the infection has not been determined.

Extradural and Subdural Abscess Following Sup-

purating Frontal Sinusitis and Osteomyelitis of the Frontal Bone.—Dr. J. H. BRYAN of Washington, D. C., presented this case. The patient, a well-nourished boy of 15, was first seen in Virginia in January, 1919, suffering from frontal sinusitis. His condition was serious and he was brought to Washington and admitted to the Episcopal Eye, Ear and Throat Hospital, where the left frontal sinus was opened, the anterior wall removed and the sinus curetted. There was always a large amount of purulent discharge from the wound, and after two weeks an abscess of the left upper lip appeared. A second operation was performed two weeks later, when the sinus was exposed and a sequestrum removed from the inner sinus wall, leaving a perforation into the cranium and exposing the dura for ⅛ inch. In April the right maxillary sinus became infected and he was again operated upon. In May, upon another examination, the whole left frontal region was found markedly swollen, pitting on pressure and exuding bloody purulent secretion through an orbital fictula. Another operation was decided upon. This was done by free incision from the outer angle to the inner angle of the orbit, and a vertical incision for an inch and a half, detaching a flap of skin and periosteum from the frontal bone as high as the eminence. A large quantity of pus and granulation tissue was found and curetted. The cavity was packed with gauze and dichloramine-T, and the wound left open. The secretions were profuse and convalescence was tedious. In July two-thirds of the external wound were allowed to close, but gauze packing was still left in on account of the profuse discharge. A probe inserted passed into the cranial cavity, but no diseased bone as found. In September the patient was in good condition, but secretions still flowed through a fistulous opening over the orbit. A cannula introduced at this time evacuated about six drachms of thick, bloody, purulent fluid. The *x*-ray showed the probe between the frontal lobe and the skull. Injection of nitrate of thorium showed a large extradural abscess between the skull and the anterior frontal lobe. This abscess was opened and drained of half an ounce of bloody purulent secretion. Granulations were removed and tincture of iodine applied. A large drainage tube was inserted. Culture of the pus showed non-hemolytic streptococci in pure growth. The patient progressed rapidly and was discharged in ten days. By December the drainage had subsided and the patient said he felt well. In January word was received that he was ill with influenza and sinusitis. In February he was reported as critically ill and he was brought to Washington again. It was then seen that he was in a markedly septic condition, temperature 103°, and swelling over the left frontal region. He was readmitted to the hospital, and was seen to be apathetic, with right nystagmus and twitching of the facial muscles. The old operative tract was opened. The sac was filled with secretion under tension. Some necrotic bone was removed from the inner table of the frontal bone. After operation the patient remained semi-comatose and developed convulsions. He died five days after operation. The neurological condition before death pointed to a lesion of the temporal lobe or tracts. Examination of the animal fluid pointed to the fact that the condition was one that was not in free communication with the spinal fluid. The acute condition was so rapid that decompression was considered inadvisable when it was possible to recognize the existent condition. At autopsy the entire left hemisphere was covered with purulent exudate over an area 8 by 5 c.m., in extent, with center at the junction of the Rolandic and Sylvian fissures. The pia-arachnoid was thick, injected and swollen. There was marked vascular injection. The frontal sinus, ethmoid cells and sphenoid were injected and swollen, the latter filled with yellow, cloudy fluid. Streptococci in short and long chains were abundant in the brain exudate.

Meningitis Due to Frontal Sinus Suppuration With a Report of Three Fatal Cases.—Dr. RALPH BUTLER of Philadelphia presented this case. Inflammation of the nasal accessory sinuses and their serious complications called for intensive study. The number of reports of intracranial involvement from nasal conditions were few as compared with those of otitic origin. In the literature only 56 cases had been reported as due to frontal sinus suppuration up to 1913, and since that date five more had been found. Meningitis, complicating either chronic or acute sinusitis was most common in the male sex and during the second and third decades. Usually it ran a rapid course and terminated fatally in five or six days. Localized meningitis might be present for some time previous. The infection might be transmitted through a congenital or carious defect in the posterior sinus wall, through the veins or lymphatics, or by osteomyelitis. It was found that colored fluid injected into the perimeningeal lymph spaces could be recovered in the lymphatic plexuses of the mucous membrane of the frontal sinus and also that the veins of the sinuses communicated with each other and through the bones with the meninges and cranial sinuses. The larger the frontal sinus, the greater the danger of intracranial complications. If purulent leptomeningitis developed the prognosis was found to be very bad. Evidence would seem to show that mortality was increased by operation on the sinuses. On account of the considerable operative risk, surgeons hesitated to resort to radical operation unless intracranial infection was suspected, or unless diseased bone was present. One should not hesitate beyond this point.

Acute Abscess of the Lateral Wall of the Laryngopharynx.—Dr. CHARLES W. RICHARDSON of Washington, D. C., made this presentation. The occurrence of abscess in the laryngopharynx was sufficiently rare to warrant special mention. This type of lesion was sometimes seen in an easily recognized relationship with the coexisting peritonsillar abscess, but in the special case described there was a normal faucial region with primary laryngopharyngeal abscess. The etiological factors in abscesses of this character were not clear; possibly the numerous lymph glands in this region became infected, or some foreign body in an article of food might have scratched the mucosa and produced infection. The symptoms were characteristic. Intense pain located just below the angle of the jaw was the first symptom; tenderness here was marked and pain in swallowing was exquisite. Profuse mucus secretion occurred, but no insalivation. Respiration was not affected, and the voice was normal. Chilly sensations were occasionally felt. The temperature was moderately septic. The patient was restless, uncomfortable, and anxious about the outcome. The local manifestations were depression of the tongue, painful, distinct swelling, protruding in on the lower pharynx at the level of the fossa navicularis, where congestion was marked. After two or three days distinct pointing, with evacuation, might take place, or the abscess might be incised at this time. The distinctive symptoms of this lesion were its sudden onset, severity of symptoms, normality of the tonsils, peculiar location, obscure etiology.

Antiquity of Antiepidemic Measures.—Cabanès, in a recently published monograph on the scourges of humanity—among which he includes bubonic plague, lepra, cholera, smallpox, and grippe—shows that most of our repressive measures were practised centuries ago. In the pestilence which raged at Nancy in 1631 it was obligatory to report new cases and to disinfect the premises of the sick. Isolation, sequestration, compulsory reporting of cases, disinfection of clothing, suppression of animals believed to transmit disease, cleansing of streets and houses—all of these were carried out in the seventeenth century. The author fills the chair of history of medicine in the University of Brussels.—*Gazette des Hôpitaux*

Encephalitis Lethargica in Spain.—Dr. Fernandez Sanz reports a series of seventeen personal cases of this malady seen in Madrid. Of this number three at least succumbed. The majority are styled primary cases, hence the so-called secondary cases should receive especial attention. The first of these was clearly an example of grippal meningo-encephalitis accompanying bronchial pneumonia but ending in recovery. The second developed in the course of influenza, but presented ocular pareses and lethargy, while the third and fourth were of the same type—typical encephalitis lethargica developing in the course of grippe. Such experience must incline the beholder to a unicistic conception of the two maladies.—*El Siglo Medicó.*

Books Received.

THE AMERICAN RED CROSS IN THE GREAT WAR. By HENRY P. DAVISON. 302 pages with illustrations. Published by The Macmillan Company, New York.

TRANSACTIONS OF THE AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION. Volume 26, (1919). 600 pages with illustrations. Published by American Medico-psychological Association.

Therapeutic Hints.

Spirit of Camphor in Hay Fever and Asthma.—Stuver tells of a blacksmith who has suffered from asthma all his life, the first attack following whooping-cough when he was nine months old. After trying all sorts of treatment, from that prescribed by eminent specialists and general practitioners to the cults and sure cures that infest the byways of medicine, all without more than temporary relief, the man used a solution of carbolic acid, camphor, and borax, applying it to the mucous membrane of the nose by means of an atomizer. Later he used spirit of camphor alone. His asthmatic attacks were always ushered in by hay fever symptoms; as soon as he felt these symptoms coming on he would pour some of the spirit of camphor in his hand, hold it to the nose and inhale freely, repeating several times if necessary to check the trouble. He had used the camphor in this way for eighteen months and during that time had not had an attack of asthma.—*Western Medical Times.*

Bromidrosis.—Isaac L. Peebles recommends the following local treatment for bromidrosis, with special reference to the feet. The parts should be cleansed night and morning. Also change shoes and socks daily; paint feet lightly twice a week with tr. iodi. Wash feet in weak solution of permanganate of potassium, about 5 grains to the basin of real warm water. Wash at bedtime. Remove feet from basin. Do not dry with towel, but allow feet to dry in the open. Next morning wash feet well in ordinary sterile water, then powder shoes and socks freely with the following powder:

℞ Acidi salicylici.....grains xx
Pulv. amyli 3iij
Pulv. talci .....℥ij
Acidi borici .....℥ij

M. Sift into shoes and stockings each morning freely.—*The Medical World.*

Infusion of Parsley in the Treatment of Gallstones.—H. Cameron Kidd cites the case of a woman over seventy years of age who had suffered for many years from gallstones. Examination by the writer during a prolonged attack revealed a large palpable mass in the region of the gallbladder, in which gallstones could be felt. Operation was advised, but the patient objected, relating the cure of a friend under similar circumstances brought about by drinking infusion of parsley. She had begun herself to take about 1½ pints daily of an infusion made by soaking a good double handful of fresh parsley leaves in cold water, which was afterward brought to the boil, strained and allowed to cool. She persevered in this treatment, which seemed to have cured her. After nearly two years she remained free from pain and sickness, and the mass in the region of the gall-bladder disappeared. She was no longer emaciated and the general condition was satisfactory. The fruit of parsley, and apparently also the whole plant, contains an essential oil, which is pretty well known under the name of "apiol" as a remedy for dysmenorrhea. Common garden parsley is recommended in the French *Codex*, in combination with other aromatic plants, as a diuretic.—*British Medical Journal.*

CHRONIC TONSILLAR INFECTIONS.*

BY H. B. ANDERSON, M.D., L.R.C.P. (London), M.R.C.S. (England)

ASSOCIATE PROFESSOR OF CLINICAL MEDICINE; SOME TIME PROFESSOR OF CLINICAL PATHOLOGY, UNIVERSITY OF TORONTO, ETC.

R. W. MANN, M.D.,

DEMONSTRATOR OF CLINICAL MEDICINE, UNIVERSITY OF TORONTO, AND

N. C. SHARPE, M.D.,

FELLOW IN PATHOLOGY, UNIVERSITY OF TORONTO.

THE great importance of diseased tonsils as foci whence infection, especially by streptococci, gains entrance to produce various systemic diseases, has been well established during recent years. Still more recent investigations of the virulent type of pneumonia, often accompanied by empyema, following measles and influenza, have shown that hemolytic and to some extent, other types of streptococci, taking advantage of the lowered systemic resistance due to the primary disease, have been largely responsible for these serious complications and the appaling mortality which resulted from them.

Numerous epidemics of severe tonsillitis have been traced to milk, contaminated by hemolytic streptococci from the udders of cows affected by garget, or milkmen suffering from tonsillar infection. Even apparently wholesome, certified milk has frequently been shown to contain hemolytic or other varieties of this organism.

The extreme facility with which streptococcal infections are carried from patient to patient in hospitals and barracks, the greater liability to pneumonia and other serious complications in measles and influenza among streptococcus carriers as compared with non-carrier, and the importance of segregating the former, are matters upon which there is marked unanimity of authoritative opinion.

Investigation of the bacteriology of the tonsils by many competent authorities has shown that commonly streptococci are found on examination of excised tonsils or materials expressed from the crypts, so much so that most investigators state that these organisms are normal inhabitants. That they are dangerous tenants, under conditions favorable to infection, is generally admitted. The degree of virulency of the three types—hemolytic, viridans, and non-hemolytic, is in the order named—the exogenous strains from milk, contact, and droplet infection being considered more virulent than the so-called normal inhabitants of the crypts.

*Read before the American Therapeutic Society at its twenty-first annual meeting, held in Philadelphia May 7 and 8, 1920.

The *Streptococcus viridans* and other non-hemolytic varieties, are more widely distributed, represent more heterogeneous groups than the hemolytic as determined by immunity reactions, and produce more local, chronic, and milder lesions. They do not call forth an active local or systemic resistance from the body's defensive mechanisms in the way of leucocytic exudate or antibodies and therefore produce infections less easily eradicated by treatment.

It is generally admitted that laboratory tests of the morphologic, cultural, and biologic characteristics of these organisms are insufficient to determine the degree of pathogenicity of a given strain. To establish in a given case whether we are dealing with a harmless saprophyte or an organism capable of producing or actually accounting for systemic symptoms, however, is a matter of the greatest practical importance to the clinician, and I believe this may most readily be done by considering the laboratory and clinical findings side by side. If these organisms are found in the tonsil, unassociated with local or systemic evidences of disease, though one would recognize certain pathogenic possibilities, he would not attribute importance to them under such circumstances, unless as possible carriers of infection to others. If, on the other hand, they are associated with definite local and systemic evidences of disease, is not one warranted, on clinical grounds, in incriminating them as the probable cause of trouble?

It will be noted that investigations on the tonsils carried out so far have been largely in *group* cases, occurring in military camps, in hospitals, or in connection with local epidemic outbreaks, with the consequent liability that the infection has been carried from patient to patient, or to those exposed to such influences as a contaminated milk supply. The cases coming under the observation of throat specialists are usually those that have local symptoms directing them, or have been referred because they are suspected of having throat trouble.

The clinician, dealing with private patients, on the other hand, comes in contact with more isolated rather than group cases, and has to study not only *local*, but the *systemic* evidences of infection, and has usually an opportunity to follow his cases over a longer period, noting the ultimate results of operative or other treatment, and thus is in a favorable position to determine many of the unsettled points regarding tonsillar infection. It is his duty in a given case to decide whether an active infection in the tonsil exists, capable of producing attendant systemic symptoms, and as he must advise the patient regarding the general plan of treatment to be followed, the question of the tonsils necessarily comes under his consideration.

The clinical evidences of disease in a patient, local and general, represent the *reaction* of the tissues to the infecting organisms, and therefore should afford the best criterion of their activity and virulency.

In order to determine the condition of the tonsils and the bacteriologic findings more generally in the population, during the past 15 months, in association with my assistants, Dr. R. W. Mann and Dr. N. C. Sharpe, the writer (Anderson) has made routine examinations of the throats of cases in office practice, comprising patients widely distributed throughout the Province of Ontario, and therefore representative of conditions more generally obtaining among the subacute and chronic, *ambulatory* sick in the community as a whole. The method of investigation in each case has included observations covering the following points:

(*a*) A careful history of previous attacks of tonsillitis; quinsy or sore throat.

(*b*) A history of any systemic disease, such as is known may arise from focal infection of the tonsils.

(*c*) Evidences of coincident infection of the teeth, sinuses, nasal cavities, etc.

(*d*) The presence of hypersecretion of the throat, pharyngitis, and the condition of the lingual and pharyngeal tonsils.

(*e*) The presence of redness, granular appearance, or thickening of the anterior pillars and adjacent soft palate.

(*f*) Noting the size and color of the tonsils, fissured, ragged, or cryptic conditions, adhesions or sealing over of the mouths of the crypts with scar tissues, interference with drainage.

(*g*) Firm pressure backwards upon the anterior pillars so as to extrude the tonsils, noting evidences of atrophy, fibrosis, edema, adhesions to the pillars and peri-tonsillar tissues, areas of inflammation in the substance of the tonsil: caseous or purulent material expressed from the crypts, peritonsillar tissues, or supratonsillar fossa, and the odor of the exudate.

(*h*) The presence, after operation, of scarred remains of the tonsil, tags, evidences of trauma, residual inflammation in the tonsillar fossæ or the pharynx, etc.

(*i*) Enlargement or tenderness of cervical lymphnodes.

(*j*) Bacteriological examination of swabs from the crypts or the cheesy or purulent exudate, expressed therefrom.

The bacteriological examination was as follows: The swabs from the tonsil crypts were streaked on glucose-human blood-agar and incubated. The plates were examined for hemolysis, 24 to 48 hours later. Stained smears were examined to identify the organisms. In all, 937 patients were carefully examined by the above methods, and of these 623, or 66 per cent, showed definite clinical evidences of tonsillar infection.

In this series, *Streptococcus viridans* was found in 260 of the 937 cases, or 27.8 per cent, though there was a marked seasonal variation, being lowest in the autumn—viz., 16 per cent in September, 4.2 per cent in October and 5.2 per cent in November, rising rapidly to 44 per cent in December, 65.3 per cent in January, and 75 per cent in February. The clinical evidences of tonsillar infection also showed a great increase during these months, and it was also believed that *Streptococcus viridans* was especially associated with a more markedly edematous inflammation, dark red in color, rather than with distinctly cryptic and purulent types, so much so that we were usually enabled to foretell this type of infection from the local appearances presented. Other nonhemolytic forms were second in order of frequency, being found in 137 cases, or 15 per cent, the percentage being lowest in the periods when the other forms were most frequent.

The *Staphylococcus aureus* was found in 114 of the 937 cases, or 12 per cent. In November, 1919, it was found in 42 per cent of 47 cases examined. This is relatively a much higher percentage than most observers have reported.

The hemolytic strepococcus was found in 79 cases, or about 0.9 per cent, being much more frequent in the autumn, winter, and spring months than in the summer—rising at times to 25 per cent of the cases examined during the former periods.

The largest percentage of the most pathogenic forms, therefore, correspond to the colder weather,

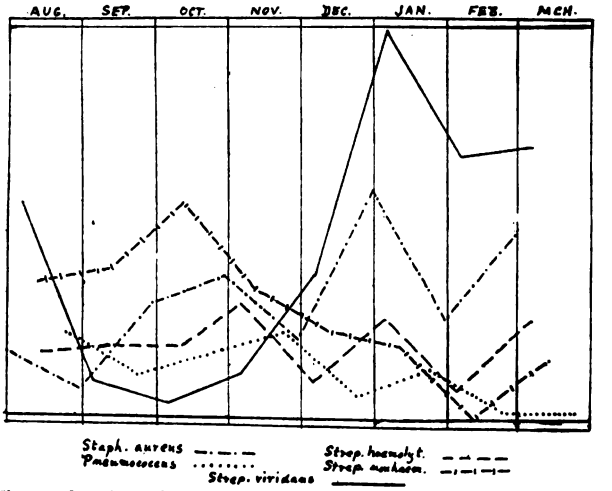

Chart showing the relative frequency of pathogenic organisms in cases of tonsillar infection from August, 1919, to March, 1920, inclusive.

indoor life, and the period when pneumonia, rheumatism, etc., are most prevalent. Two or more form not infrequently were isolated from the same case. Less frequently bacteriological findings were diphtheroid baccilli, pneumococci, *Micrococcus catarrhalis*, etc.

Considering together the results of our clinical and bacteriologic investigations, they lead to the conclusion that a large percentage of the adult population of the class seeking private consultation present definite evidences of tonsillar disease, associated with the presence of pathogenic oganisms, producing or capable of producing, under conditions favorable to general infection, more or less serious systemic symptoms. In our experience in the chronically ill, typically healthy tonsils are the exception, rather than the rule. In fact, it would appear that more or less evidence of active tonsillar infection is about as common in this class as recent investigations have shown to be the case with oral infection. So often does one find in patients chronically ill evidences of definite infection in the tonsils that one might almost consider it as a concomitant of the normal process of atrophy, or that a chronic infection of

low intensity is designed to stimulate a systemic response which renders the subject refractory to more serious attacks. The latter view point has been elaborated in an interesting manner.

It seems to us, however, that we may too readily give a certificate of character as normal inhabitants to potentially dangerous bacterial invaders of the tonsils.

There are certain conditions to which the general population is exposed at the present time, which predispose to infection of the tonsils and help to explain its frequency. Those who have studied the condition are aware of the difficulty of ridding the tonsils of infection, once it has been well established (Billings). Their exposure not only to pathogenic bacteria in food and drink, but to local irritation, the low vitality of the tissue itself, the long, sinuous crypts, so readily occluded so as to interfere with drainage—all are favorable to continuance of infection.

The common diseases of childhood—scarlet fever, measles, and diphtheria—are practically always associated with throat involvement, due to streptococci, and the same may be said of postnasal and sinus disease draining into the nasopharynx. The oral infection with which *Streptococcus viridans* is constantly associated, not only in the neglected mouths of the poor, but in a more serious form in the mechanically maintained infections so commonly found among the well-to-do, are foci whence infection extends to the surrounding tissues, including the tonsils.

The kissing of children by adults with infected mouths is another obvious means of transmission of infection to the tonsils. Incomplete operations in children, leaving stumps and tags and the producing of trauma and scar tissue, are frequent causes for the persistence of chronic infection in adult life. Even after complete enucleation, there is often an hypertrophy of lymphoid remains in the nasopharynx, that is the seat of recurrent infection.

Whether the infected tonsils produce symptoms or not, apart from the degree of systemic resistance, is often a question of drainage. The action of the palatoglossus and palatopharyngeus muscles, in mechanically compressing the tonsils during deglutition and the abundant secretion of mucus to destroy bacteria and wash out the crypts, are among the means which nature has provided to ward off infection, but where previous inflammation has occluded the crypts, sealed over their openings by scar tissue, or produced adhesions, these means become less effective. Thus the small, concealed, atrophic, adherent tonsils and stumps and tags left after incomplete operation, which may present little evidence of disease on superficial examination, are commonly the seat of the most serious type of infection. The atrophic tonsil itself is often evidence of long continued infection, and, as Carmichael has stated, tonsils having undergone repeated attacks of inflammation, with resulting fibrosis and loss of nearly all the glandular tissue, finally offer no resistance to pathogenic bacteria. We wish to protest against the frequent assumption as unwarranted on pathological grounds, that a given tonsillar infection is clinically unimportant because the amount of tissue involved is not extensive. Obviously the virulence of the infecting organism, the patient's resistance and the question of drainage may be of greater moment.

Often very firm and long continued pressure on the pillars is necessary in order to express the pus sealed in by firm adhesions. Infection may often be demonstrated by this means which would be overlooked by retraction of the pillars or bringing the tonsils into view by a tenaculum. Direct palpation of the tonsils is a procedure too often neglected in routine examination for evidences of infection. These are the cases where chronic enlargement and tenderness of the upper cervical lymphnodes is of most clinical significance though many cases of definite tonsillar infection do not show lymphnode enlargement, and it must be remembered that all parts of the pharyngeal ring do not drain into glands readily accessible to palpation. At times, patients gave a history of recurrent attacks of tonsillitis, quinsy or sore throat, indicative of persistent infection, but in many cases where investigation has revealed definite evidence of disease, the patient had complained of no local symptoms. The throat of inhalers of cigarette smoke and the so-called "smoker's throat," usually showed clinical evidence of infected tonsils and the throats of soldiers seriously exposed to the effects of chlorine and othe irritant gases, commonly showed chronic tonsillar infection.

The persistence of evidences of residual infection about the pillars, in the tonsillar fossæ and those of the pharynx, after enucleation, is very common, suggesting that at times we take too mechanical a view of the possibilities of removing an infection which has extended more widely into the surrounding tissues or adjacent lymphnodes or produced systemic disease. This is especially the case where a coincident oral or sinus infection has not been cleared up as a preliminary to operation, when the general health is below par, or when some systemic disease, such as diabetes, gout, or acid intoxication, or digestive disease exists. These factors help to explain some of the disappointing results following operation.

The rapidity with which marked improvement in the condition of the tonsils follows when a diabetic patient has become sugar-free, as well as the rapid reduction in carbohydrate tolerance coincident with an acute exacerbation of a tonsillar infection, emphasize the importance of constitutional conditions which reduce systemic resistance.

The presence of certain symptoms of systemic disease may be an important indication of the activity of a local tonsillar infection in a given case. In 574 cases in our series, the patients presented the following associated conditions:

1. Rheumatic group, including arthritis, lumbago, sciatic and other pains, neuritis, etc. .....166 cases, or 27.1 per cent
2. Cardiovascular, including valvular disease, hypertension, myocardial disease, angina pectoris .....115 cases, or 20 per cent
3. Goitre (Simple, 80; exophthalmic 20) .....100 cases, or 17.4 per cent
4. Gastro-intestinal, including appendicitis, gastric and duodenal ulcer, hyperacidity, gastric atony, cholecystitis and gallstone disease, unspecified indigestion.....
   116 cases, or 20 per cent

5. Diabetes and glycosuria..28 cases, or 4 per cent
6. Respiratory diseases, including bronchitis, asthma, and pleurisy ...30 cases, or 5.4 per cent

Oral sepsis was noted in 320 cases or 55 per cent, but if we included the edentulous, in whom previous serious infection obviously had existed, the percentage would have been higher. It may further be stated that healthy tonsils are rarely if ever found where the mouth is seriously infected.

There is a notable lack of harmony among observers as to the relative frequency of the different pyogenic organisms found in the tonsils, apparently depending upon the bacteriological technique employed, whether the examination has been of excised tonsils or of swabs from the surface or of the crypts, whether during epidemics of tonsillitis, measles, or influenza, etc., whether among group cases as in barracks, hospitals, and schools, or among more widely scattered individuals, and according to the season of the year. A point of great importance, moreover, which has not received the attention it obviously deserves, is whether the cultures have been made from healthy or clinically diseased tonsils, as has been in the case of the epidemic diseases before mentioned, and in the statistics of Smillie, Tongs, and others. Conclusions regarding the normal flora can obviously not be drawn from the study of diseased tonsils.

These factors offer a reasonable explanation of the widely divergent results reported by competent investigators as to the frequency with which *Streptococcus hemolyticus* is found, varying from 1 per cent, as reported by Smillie, to 100 per cent reported by Davis.

If definite tonsillar infection is as common as our investigations have led us to conclude, the importance of our endeavoring to control, as far as possible, the causes producing it, is obvious; but some of these are so bound up with inevitable social conditions that the problem is a difficult one. Others, however, are more possible of control, as milk supply, oral and sinus infection, incomplete operations, unnecessary trauma, etc.

The maintenance of the highest degree of general health, the treatment of constitutional conditions which lower resistance, the value of alkalies and similar means, one need not discuss. Opinion as to the ineffectiveness of vaccines is very general, and local applications, such as iodine, argyrol, chlorine preparations, etc., are equally disappointing as means of clearing up a chronic infection. Irritants should be avoided and the best results apparently are obtained from bland, alkaline remedies, or physiological saline solutions. Preliminary attention to oral and other foci of infection certainly would give nonoperative measures a better chance and the fact that improvement in the condition of the tonsils in the summer months with the lesser frequency of pathogenic organisms in cultures, suggests a tendency to spontaneous cure under favorable conditions.

The use of the cautery and caustic drugs, by increasing the amount of scar tissue and thus interfering with drainage, appears difficult to justify on pathological grounds. These, like partial removal of the diseased tonsils, may be followed by temporary improvements, but often the ultimate results are worse than the original condition. Complete enucleation, with the least possible trauma, apparently gives the best ultimate results. The removal of oral, sinus, nasal, and other local foci of infection is a prerequisite to successful operative treatment. The continuance of general and local treatment in order to get rid of residual infection is too often overlooked.

The decision as to the necessity for operation must be made in the individual case after careful consideration of the local and systemic evidences of infection, including bacteriological examination, and in regard to this there appears in practice a marked divergence of opinion. The nature of the infection and the question of drainage appear to be all important, much more than the size or outward appearance of the tonsil. Moreover, conclusions as to the actual size of the tonsils, based on their prominence on throat examination, are known to be erroneous, since the adherent tonsil, when concealed in a deep fossa or behind a prominent plica, is quite often much larger than outward appearances suggest.

Different attitudes regarding operation are illustrated by a case which I saw a few days ago in which a prominent throat specialist, after examination, said the tonsils were infected, but not sufficiently so to call for enucleation.

The patient was a vigorous, well-developed woman, a vocalist, aged 37, and her symptoms, consisting of recurrent attacks of laryngitis and bronchitis, pains about the angle of the jaw and in the neck, for which she had had recourse to osteopathic treatment, rhonchi in the apex of the right lung, producing an uncomfortable sensation on breathing, had followed an attack of tonsillitis three years ago. Radiographic examination of the chest was negative, she had no expectoration and no fever. The tonsils were small, and the pillars red. They were healthy looking on a superficial examination, but were so adherent that one could not extrude them by firm pressure. A small amount of caseopurulent matter was obtained after prolonged pressure and culture from this showed *Staphylococcus aureus* and *Streptococcus viridans*. The upper cervical glands were slightly enlarged and tender.

This is cited as illustrating a type of case in which the clinical findings, we believe, offer an indication for enucleation as the proper method of treatment, but in which the local evidences are so unobtrusive, that the opinion is frequently given by the specialist that there is not sufficient infection to warrant it—a view which we do not think is in accord with a proper understanding of the pathological condition or the clinical findings. In dealing with infection, the virulence of the organisms, the local and systemic resistance of the patient, and the question of drainage are more important than the extent of the area involved.

In conclusion, we wish to say that our object has been to bring up numerous practical considerations which confront the clinician, with a view to eliciting the opinions and practice of the members of this Society in dealing with them. We have dealt with the question from the standpoint of the clinician rather than of the throat specialist, believing that from this angle, the whole question may be studied in its widest relations.

184 Bloor Street, East.

THE ANATOMY, PHYSIOLOGY, AND PATHOLOGY OF THE TONSILLAR STRUCTURES IN RELATION TO CRYPTOGENIC INFECTIONS *

By GEORGE B. WOOD, M.D.,

PHILADELPHIA.

I PROPOSE in this paper to review as succinctly as possible, various facts concerning the anatomy, physiology and pathology of the tonsil structures and their relation to tonsillar infection. The question which I will strive to answer is: "Do the tonsils show any peculiar anatomical structure or possess any specific physiology or undergo pathologic changes which would make them more liable to act as a gateway of infection than other structures of the nose and throat?"

The tonsils are simply accumulations of lymphoid tissue occurring in certain angles of the throat and are more important than the lymph follicles and other lymphoid structures found in the nose and pharynx only because of their greater size. The pharyngeal tonsil is situated in the vault of the pharynx and when enlarged is commonly termed "adenoids." The faucial or palatal tonsils occupy a space between the throat and the mouth bounded in front by the anterior pillar, and behind by the posterior pillar of the fauces. The lingual tonsil is found at the base of the tongue just above and in front of the epiglottis. Because of their size and the very frequently embedded character which they show, the faucial tonsils must be given precedence in importance as a source of cryptic infection, yet all of the tonsillar tissues of the throat show a very similar histology, varying chiefly in the character of the epithelium lining the crypts. There are four elements making up the tonsillar structure: the capsule, the follicles, the interfollicular tissue, and the crypts. The fibrous capsule which separates the tonsil from the underlying musculature has extensions called trabeculæ, which pass into the substance of the tonsil and act as a supporting frame-work to the parenchyma proper. These trabeculæ contain the blood-vessels and lympathics. The lympathic vessels of the tonsil are all efferent in function, as the substance of the tonsil does not possess afferent lymph vessels. The parenchyma of the tonsil consists of the germinating follicles and the interfollicular tissue. The germinating follicles are made up chiefly of accumulations of large mononuclear cells which in the active functioning tonsil are undergoing rapid mitotic division. This mitosis is productive of small lymphoid cells which accumulate around the periphery of the follicle, becoming gradually dispersed throughout the interfollicular substance. The lymph vessels of the trabeculæ are frequently found filled with these lymphoid cells, and in very active tonsils we occasionally see them in a crypt where they have obtained entrance by rupturing the cryptal epithelium. Supporting both the follicles and the interfollicular substance is a reticulum formerly supposed to be derived from the connective tissue, and frequently spoken of as endothelial. Lately, however, there has been brought forward some evidence to support the belief that this reticulum is, in part at least, derived from the epithelium of the tonsillar crypts.

The most peculiar anatomical feature of the tonsil is the crypt, which is formed by an invagination of the surface epithelium. The epithelium of the crypt differs, however, from the surface epithelium in that it has no sub-epithelial connective tissue, and in many places no basement membrane. Further, the basal cells undergo a disintegration, so that in many places an intact layer of epithelium is found only in the extreme surface cells. In the tonsil which has become fully developed, the crypts or lacunæ are found penetrating to the extreme depth of the tonsil, invading its structure so that it is practically impossible to cut into the tonsil without opening one or more of the crypts. If we review its histogensis, we will find that the earliest evidence of the tonsillar structure is the change in the epithelium which later develops into the crypt, and even at this early date, the peculiar disintegration of the basal cells of the epithelium is very strikingly seen. Apparently, therefore, the cryptal epithelium does not offer as strong a mechanical barrier against the invasion of outside influences as does the intact epithelium of the surface of the tonsil and neighboring structures.

The lymphatic drainage of the tonsils is as follows: The tonsil parenchyma possesses spaces which are continuous with the lymph radicals, which latter terminate in the efferent lymph vessels situated in the trabeculæ. The direction of the lymph current of the tonsil is as a rule, from the crypt and germinating follicles toward the lymph vessels in the trabeculæ. From the trabeculæ, the lymph vessels pass to the capsule, finding their way to the deep cervical lymph nodes of the neck. The lymphatics from the pharyngeal tonsil penetrate the posterior pharyngeal wall and pass back under the big vessels of the neck to the posterior group of the deep cervical lymph nodes, while the lymphatics from the faucial tonsils pass in front of the big vessels to the anterior group of the deep glands, especially to one lymph node which is usually larger than the others, and placed just above the posterior belly of the digastric muscle. This lymph node is the one that is so frequently found enlarged just below and back of the angle of the jaw.

As to the physiology of the tonsillar structure, almost every conceivable function has been assigned to it. For instance, the tonsils have been said to excrete certain cells that tend to prevent infection, that they develop an internal secretion like that of the suprarenal glands, that they aid in salivary digestion, and that they help in the production of general immunity by the absorption of toxins from the crypts. This latter may at times occur, though in a small series of observations I was unable to prove it. A number of observers such as, Schoenmann, Lenhart and later Henke, believe that they have sufficient experimental evidence to show that the tonsils act as excretory organs for foreign elements which may be brought to the tonsils by way of the lymphatics. Henke's work was based mostly on his observations made in both animal and human experiments in which minute, inert, foreign particles, such as carbon and Chinese ink, when injected into the gums or into the nasal mucosa were later

*Read at the Twenty-first Annual Meeting of the American Therapeutic Society, held in Philadelphia, May 7 and 8, 1920.

found passing out through the tonsillar crypts. Because of these observations he claims that tonsillitis is caused by virulent organisms being carried to the tonsillar parenchyma by the lymphatics and is rarely if ever due to surface infection, further, that the tonsillitis occurring in joint rheumatism, endocarditis, and other septic conditions is the result of and not the cause of the general condition.

Karl Amersbach, stimulated apparently by Henke's work, carried out a more complete and more carefully made series of similar experiments with an absolutely opposite result, and he believes that Henke is not only guilty of faulty technic, but that his published observations do not warrant his conclusions. In quite an elaborate study of the lymph drainage of the accessory nasal sinuses, W. B. Mullin, in all his experiments, did not succeed in injecting the tonsils, even when the palate or the nasopharynx was involved, and says that, therefore, the region draining into the tonsils in the animals used in his experiments must at least be very limited. There is little doubt that Henke's idea is entirely wrong and further, that it must be considered as an established fact that the lymph drainage of the tonsil is strictly efferent, and that the tonsils cannot be considered in any way as excretory organs.

The only tonsillar function which has stood the test of time and observation is the production of the lymphoid cells in the germinating follicles. Personally, I also believe that some day we shall find that the peculiar disintegration of the epithelial cells of the tonsillar crypts may play some rôle in the formation of the various free cellular bodies of the blood and tissues.

It would seem, therefore, that the tonsil is important to the welfare of the body only as far as the production of lymphocytes is concerned and is only valuable at such time in life when this function is not being properly cared for by other organs. Its function is very similar to that of the thymus gland and it is interesting to note that its development follows closely after the involution of the thymus. Later on, the tonsillar structures tend to involute, gradually losing their activity as the other blood forming organs develop. I have never been able, however, to prove to myself that the absence of the tonsillar structures of the throat, due to operative interference, had any deleterious action on the health or growth of the individual, no matter at what age they were removed, though I try to avoid operating before two years of age.

The tonsils, however, possess other properties which may be more properly termed pathologic than physiologic, for although the property in itself is not of or pertaining to a disease, the exercise of that property may result in the production of pathologic conditions. For instance, as the tonsil grows the crypts are elongated and the mouths may become more or less constricted, resulting in the retention of debris in the tonsillar lacunæ which may develop into a culture media for pathogenic organisms. Also it has been shown by numerous observers that for some reason the cryptal epithelium will permit inert foreign bodies to pass between the cells of said epithelium so that they are absorbed into the interfollicular tissue and, gaining access to the lymph radicals, finally enter the efferent lymph vessels. This property of absorbing foreign material has been sufficiently substantiated by the work of men such as Goodale of Boston, Kayser, Hendelsohm, Piera, and other careful observers, so that we must accept it as an established fact.

There is, however, a marked difference in the behavior of the tonsil toward the absorption of inert material and of living organisms. If we examine the crypts of healthy tonsils we may find a large number of cocci and bacilli in the lumen of the crypt but none in the substance of the tonsil itself, not even below the first layer of vital epithelial cells. It would seem that, in what we might term the state of health, there is a distinct negative chemotaxis between the bacteria and the living tissue. However, under certain circumstances this vital resistance becomes lessened and pathogenic organisms will then penetrate through the cryptal epithelium and produce disease of the tonsil. Further, certain types of bacteria may pass not only through the epithelium into the tonsil, but may also follow the course of inert foreign bodies and gain access to the regionary lymph nodes without visible lesion in the tonsil. It is probable, however, that the great majority of tonsillar infections follow after the infecting organism has first made a breach in vital cryptal epithelium. This mode of tonsillar infection we will consider briefly later in taking up the question of the pathology of tonsillitis.

In tuberculosis, the tonsils are more readily infected than almost any other tissue in the body, and in tuberculosis of the cervical lymph nodes they are the portals of entrance in probably 90 per cent. of the cases. Primary tuberculosis of the tonsils will be found in approximately 6 per cent. of all tonsils removed routinely. This proportion was according to my own examinations, and was about the ratio found by other observers whose statistics I collected in 1904. Twenty-three different observers reported 1,671 cases examined, and primary tuberculosis of the tonsils was found 88 times, giving an occurrence of 5-2/10 per cent., and I believe that if a more careful histologic examination of the tonsils had been made, a greater percentage would have been obtained. The tonsil is more frequently infected secondarily in pulmonary tuberculosis than any other organ, and from a study of autopsies at the Phipps Institute, I found that practically every patient who came to autopsy as the result of pulmonary tuberculosis showed some lesion in the faucial tonsil. In a series of studies of the tonsils of hogs, I found that tuberculosis of the tonsils could be easily produced by gently swabbing the surface of the tonsil with a culture of virulent bovine tubercule bacilli, and that the disease then spread to the regionary lymph nodes. Though many of these animals developed tuberculosis in other organs, the tonsil was always infected without lesion in any other part of the pharyngeal mucosa, and that the cervical adenitis was always more advanced than any other tuberculous area. It was interesting to note that although the tonsil was involved as early or even earlier than the cervical lymph nodes, the disease progressed much more rapidly in the lymph nodes than it did in the tonsil. In some of the experiments the presence of

the tubercle bacilli in the lymph nodes of the neck was demonstrated before any lesion could be detected in the tonsil itself. In other words, the organism had passed through the healthy tonsil and was arrested in its forward progress only when it had gained access to the regionary lymph node. This, of course, was an extremely interesting finding as it demonstrated without any reasonable doubt that there exists an open pathway for infection through the tonsil, at least as far as the tubercle bacilli are concerned. I did not, however, actually see the tubercle bacilli going through the tonsil structure and it remained for a series of experiments with the anthrax bacillus to furnish this last evidence of the vulnerability of the tonsil to certain types of bacteria. In these experiments, the tonsils were inoculated by swabbing the surface with an emulsion of anthrax bacilli. It was shown that the tonsils of the hog are more readily infected by the anthrax bacillus than any other portion of the buccal or pharyngeal mucosa and that the bacillus penetrates through the cryptal and not the surface epithelium. Further, the anthrax bacillus gains access to the parenchyma of the tonsil by passing through the living, unaltered cryptal epithelium. After the bacilli had entered the tonsil substance, they apparently passed in the direction of the lymphatic vessels of the trabeculæ though they also tended to congregate around the germinating follicles. Only very few were found in the interfollicular tissue.

In the experiments with both the tubercle bacillus and the bacillus of anthrax, the infection was from the surface of the tonsil, not from the throat or supposititious afferent lymph-vessels; of this, there can be no doubt. Also, while it was supposed, and with a good deal of reason, that the tubercle bacillus penetrated through the normal epithelium of the crypt, it was absolutely demonstrated that this was the source of entrance for the anthrax organism.

However, it is probable that in the majority of infections of the tonsil there has been some break in the epithelium due to the necrotic action of the bacterial toxins which have developed from the organisms in the lumen of the crypt. It is possible, however, that a certain amount of toxic material is absorbed directly through normal cryptal epithelium, especially in those cases of chronic tonsillar disease in which the lumen of the crypt has been obliterated, forming within the tonsil a retention cyst of necrotic infected material.

In acute tonsillitis, the tonsil is infected in the following manner. The infecting organism gains access to the crypt, producing there, by its growth, sufficient irritation to cause a distinct reaction in the epithelium. This reaction is manifest by a proliferation of the epithelial cells, as shown by the increase of desquamation and of penetration of the basal cells into the tonsil parenchyma and the presence of mitotic figures in the epithelial cells. If the infecting organism is not of sufficient virulence, this proliferation of the epithelium may prevent invasion, and we have as the result a simple parenchymatous tonsillitis. When the toxic action, however, is more severe, certain portions of the epithelium become necrotic and this process may progress until the parenchyma of the tonsil is opened to the infecting bacteria. The bacteria then passes with the current of the interfollicular tissue toward the lymphatics, or they may become arrested in the germinating follicles where, through their development, abscess formation takes place in the follicle which later ruptures into a neighboring crypt, producing a purulent discharge at the mouth of the crypt which is so characteristic of suppurative tonsillitis. The organisms that reach the efferent lymph vessels are carried to the regionary lymph nodes producing the lymph adenitis which is associated with all severe cases of tonsillitis.

In summing up the evidence which I have tried to present in these rather dogmatic statements, it would seem that systemic infection, because of the peculiar anatomy of the crypts, and because of the peculiar property of absorbing substances from its crypts, and of the extremely low resisting quality of the cryptal epithelium to bacterial attacks, takes place more readily through the tonsillar structures than through any other portion of the upper respiratory tract. That the tonsil itself is not destroyed by the numerous invasions to which it is subjected must be ascribed to its great power of recuperation and regeneration.

1830 SPRUCE STREET.

THE THERAPEUTICS OF BENZOSULPHINIDE.*

BY REYNOLD WEBB WILCOX, M.D., D.C.L.,
NEW YORK.
PRESIDENT OF THE AMERICAN COLLEGE OF PHYSICIANS.

THIS remedy, discovered in the laboratory of Remsen in 1879, has been in use for more than forty years, chiefly as a condiment. It was incorporated in the Eighth Edition of the United States Pharmacopœia, which became official on September 1, 1905, and its sodium salt was added to the Ninth Edition, which became official on September 1, 1916.

Benzosulphinide ($C_7H_5O_3$ NS or $C_6H_4SO_2$. CONH = 183.12) is the anhydride of orthosulphamide — benzoic acid (Benzoylsulphonicimide.) Its synonyms are: Glusidum, saccharin, orthosulphamide, benzoic anhydride, and glucimide.

Source.—It is obtained from toluene, $C_6H_5CH_3$, a derivative of coal tar. The toluene is treated with concentrated sulphuric acid at 100°C. (212°F.), by which results in the formation of Ortho- and Para-sulphonic acids; these are first converted into calcium salts and then, by the use of sodium carbonate, into sodium salts. From these a mixture of ortho- and para-toluene-sulphochlorides is obtained by the action of phosphorus pentachloride; upon thoroughly cooling the mixture, the para-modification crystallizes out and is thus separated. From the other isomeric chlorides, ortho-toluene-sulphamide is formed by means of dry ammonia gas. This sulphamide is next oxidized by potassium permanganate, converting it into potassium ortho-sulphamide-benzoate, the solution of which is freed from precipitated manganese dioxide and decomposed by means of an acid; instead of separating as free ortho-sulphamide-benzoic acid, the latter splits up

*Read before the American Therapeutic Society at its twenty-first annual meeting at Philadelphia, Pa., on May 8, 1920.

into its anhydride, which is known as saccharin, and water.

Characters.—White crystals or a white crystalline powder, odorless or having a faint aromatic odor, and having an intensely sweet taste even in dilute solutions (1 of saccharin in sweetening power being equal to 300 of cane sugar.

Solubility.—In 290 parts of water and 25 parts of boiling water; in 31 parts of alcohol; slightly soluble in chloroform or ether; easily dissolved by ammonia water, or alkali hydroxide solutions; also by a solution of sodium bicarbonate, with the evolution of carbon dioxide.

Impurities.—Glucose, milk sugar, benzoic and salicylic acids, ammonium compounds, carbohydrates, inorganic impurities. Commercial saccharin is not a pure or uniform product; it often contains less than 50 per cent of actual saccharin.

Dose.—0.200 gm. = 200 milligram (3 gr.).

Sodium Benzosulphimide is the sodium salt ($Na\ C_7H_4O_3NS + 2\ H_2O = 241.14$), of Benzosulphimide. Its synonyms are Sodium-Saccharin, and Soluble Saccharin.

Source.—By neutralizing an aqueous solution of Benzosulphimide with Sodium Carbonate or Bicarbonate and slowly crystallizing the solution.

Characters.—Colorless rhombic prisms or a white crystalline powder; odorless or having a faint aromatic odor and an intensely sweet taste, even in dilute solutions (1 of soluble saccharin, in sweetening power, being equal to about 500 of cane sugar); somewhat efflorescent.

Impurities.—The same as for Benzosulphinide, with the addition of benzoates and salicylates.

Dose.—0.200 gm. = 200 milligram (3 gr.).

Action of Benzosulphinide and Sodium Benzosulphinide.—These are antiseptic, but as such are of very limited use because their properties in this direction are not marked. Their principal use is as a sweetening agent, the sodium salt being the preparation usually employed. They are not foods, but condiments, which, because they have no action upon any organ, tissue, or function of the body are absolutely harmless. They are eliminated in the urine and saliva, and, after the ingestion of large amounts, by the bowel, without change.

Therapeutics of Benzosulphinide and Sodium Benzosulphinide.—Sodium Benzosulphinide is quite generally employed as a substitute for sugar when from any cause this cannot be taken or its use must be limited.

Diabetes mellitus.—Benzosulphinide may be used in tablets for sweetening tea or coffee, 1/10 gr. (.006 gm.) to ½ gr. (.03 gm.) to a cup is sufficient Inasmuch as this substance is largely excreted into the saliva, unless small amounts are used, a disagreeable taste in the mouth may be established. It has been demonstrated that even when long-continued, its use does not interfere with the action of the ptyalic, peptic, tryptic or lipoclastic enzymes. Small daily amounts (5 gr., 0.3 gm.) may be taken during long periods of time (months) by normal adults without any detriment to health ascertainable by all available methods of study. It is believed, however, that relatively large doses, especially above 15 gr. (1 gm.), if continued for months, are liable to induce disturbances of digestion, but this amount is likely never to be reached, even if taken with foods to which it has been added.

Obesity.—It is useful in satisfying the craving for sugar and so rendering more tolerable the reduction of the food ingested.

Gout.—In limiting the protein intake, usually a desire for a larger ingestion of carbohydrates is established inasmuch as the successful dietetic treatment of this disease requires not only the regulation of the quality but as well the limitation of the quantity of the food, saccharin is valuable in replacing sugar as a sweetening agent.

Digestive and Metabolic Disturbances.—The fermentation set up by cane sugar and the consequent disturbances of nutrition, result in this being the ailment most frequently interdicted. In addition, the auto-intoxication is distinctly harmful. The various results of faulty metabolism commonly known as rheumatism are often obviated by the avoidance of sugar and its replacement by saccharin, to the marked benefit of the patient. New-born infants, before lactation has been established in the mother, should receive cool water to which saccharin—in from 1 to two one-hundredths of one per cent—has been added, thus insuring the proper ingestion of water and avoiding the alimentary disturbances so frequently caused by the administration of sugared water. Saccharin to the amount daily of one grain (0.06 gm.), thus administered, is routine practice.

Benzosulphinide has been used as an internal antiseptic in cystitis with ammoniacal urine, and has been commended as a lotion in aphthous stomatitis —replacing the ancient borax and honey solution which is objectionable because of the honey, and in ozena.

My personal observations with saccharin began in 1884, when it was discovered that a member of my family was afflicted with diabetes mellitus. Upon complaint that it tasted bitter instead of sweet, I undertook by personal experimentation to ascertain at what amount the bitter taste would appear, and I found that up to a daily amount of 15 grains (1 gm.) could be taken without provoking a permanent taste of bitterness, until that amount had been taken for about two weeks. A daily amount of 5 grains (0.30 gm.) continued over many weeks never produced any disagreeable (mawkish) nor bitter taste. This amount was chosen because it represents, in sweetening power 5 ounces (150 gm.) of cane sugar, which is usually the limit of sugar tolerance for the adult; so that for a person who uses it for all purposes—tea, coffee, in puddings, pastry, cereals, etc.—for which sugar would be used for sweetening, saccharin can be employed in its place without producing any disagreeable taste whatever.

Then I began a series of experiments with a daily amount of 10 grains (0.60 gm.) about one-half of which is about all that can be used in foods or drinks which are ordinarily sweetened with sugar, so that the remainder was taken in a capsule. After about two weeks, I observed that when food was taken with saccharin, I would notice a bitter taste in my mouth, which, however, was persistent for only a few days after ceasing its use. It will be noted that this is more than the amount set down in the U. S. Pharmacopœia—which is 3 gr. (0.20 gm.), and as three doses daily would amount to 9 gr.

(0.60 gm.). The result of weeks-long administration of 15 gr. (1 gm.) daily of saccharin resulted simply and solely in a permanent bitter taste in the mouth. When the report of the Remsen Board appeared in 1912 and confirmed my personal observations, I ceased experimentation. For practically thirty-six years I have advised the use of saccharin to replace sugar when the latter is contraindicated, to whatever amount is agreeable to the taste, knowing that 5 grains (0.30 gm.) represents in sweetening power the maximum amount of cane sugar which can be safely ingested, and that this amount is not sufficient to produce any disagreeable taste or any physiological effect whatever. Its use as a condiment—a food accessory to make it more appetizing or more palatable—is absolutely without any harmful effects, no matter how long the period of its use.

The widespread and still increasing use of saccharin as a condiment has led to various efforts to limit or abolish its use. Generally speaking, the basis of these endeavors has been that it is harmful in itself or that by its presence it lowers the value and impairs the quality of foods sweetened by it. In general it is employed commercially in non-alcoholic beverages—the so-called soft drinks—in which it serves a double purpose: it avoids the fermentation which is likely to arise if sugar is employed for sweetening purposes and which produces unsightly and unpalatable mixtures and makes them more acceptable beverages in that they better satisfy thirst if saccharin, instead of sugar, is used. The amount generally employed is one one-hundredth of one per cent. To ingest a quantity of saccharin which would equal the daily amount authorized by the Pharmacopœia, about eight quart (liter) bottles of the commercial size would necessarily be drunk, which quantity is obviously unlikely to be taken. In preserved (canned) vegetables which require to be sweetened to meet popular approval—for instance, corn—saccharin is preferable in that the brown color which sugar develops during the process of preserving is avoided. In various sweet food products—as jellies and jams—the substitution of saccharin for sugar would be illegal because the product would be misbranded—not because it contains saccharin but because it is not jelly or jam, the sugar content, about one-half, having been prescribed by regulation. In its use in pastry no amounts could be ingested which would cause even a bitter taste because the desire for sweetness would be satisfied long before the upper limit of sugar tolerance was reached. Should the manufacturer add more of saccharin than is necessary for sweetness, he would destroy the market for his wares.

Recent investigations have shown that there is not any pastry product which neutralizes the sweetening power of saccharin as compared with sugar, so that proportionately more of the former would necessarily be used to produce the same amount of sweetness. Four decades have passed during which no instance of harm has resulted even from enormous amounts ingested at one time (75 gr.—5.50 gm.) or from long-continued use of amounts equal in sweetening power of sugar to the upper limit of tolerance, nor indeed to amounts far in excess of the possibility of its introduction in food—the quantity of which is limited only by the capacity of the individual, or by ingestion in capsules in daily amount of 15 gr. (1 gm.). It has been demonstrated that saccharin is absolutely harmless, and the only untoward effect of its ingestion—namely, the disagreeable bitter taste—results only from amounts that are entirely unnecessary in its use as a condiment. Its use can never be unrestricted, because the unpleasant taste developed after the ingestion of unnecessary amounts limits its employment. As a condiment, it is absolutely fool-proof.

In regard to the second proposition—that it lowers the value and impairs the quality of foods sweetened by it, the statement is fair in that when saccharin, which has no food value, is substituted for sugar which has food value; the food value of the substance is lowered just in proportion as sugar is lessened in quantity. On the other hand, since many other carbohydrates—flour, for example—have a higher caloric value than sugar, finished products which are sold by weight—as cookies, for instance—would have a higher caloric value if sweetened by saccharin instead of sugar, and this increased caloric value would be increased by precisely the difference between the caloric values of sugar and flour.

That saccharin impairs the quality of foods sweetened by it has been abandoned as entirely untenable. Simply as a sweetener for foods which are ordinarily sweetened, it is absolutely harmless and is often the condiment of choice, which by rendering food more appetizing and more palatable increases its ingestion.

Joslin, in his "Diabetic Manual," 1918, page 19, states that "in the United States between 1800 and 1810, the average consumption of sugar *per capita* was eleven pounds per year; between 1910 and 1917, this amount has risen to 73 pounds; and Hoover estimates that for the year 1918 it will be 90 pounds. This last amount is nearly four ounces (120 gm.) per day, which closely approximates the sugar tolerance of the organism." Joslin also remarks that diabetes was four times as prevalent in Boston in 1918 as it was in 1890, and twice as prevalent in the registration area of the United States as in 1900. In his "Treatment of Diabetes," 1916, p. 19, the very suggestive statement is found: "If diabetes should continue to increase in the next thirty years at the same rate statistics show it has increased in the last thirty years, it would rival tuberculosis as a cause of death, and if this rate progresses for another generation diabetes would be responsible for almost the entire mortality of the world."

Evidently, if we are to escape the serious menace to health from the inordinate consumption of sugar and at the same time satisfy the "sweet tooth" of the community the proper use of saccharin as a condiment—which has been demonstrated to be absolutely harmless and as a sweetening agent is nearly perfect, its only drawback being the bitterness provoked by unnecessary quantities—must be encouraged by all scientific physicians.

679 Madison Avenue.

Value of Cartesian Physiology.—Descartes has been claimed as the father of physiology by Huxley, Richet, and other prominent scientists because of his mechanistic conception of life, although he has been exculpated by others of materialism.—*Le Progrès Médical.*

NEW PROCEDURE FOR THE PREVENTION OF SPINAL PUNCTURE HEADACHE.*

By GUSTAV BAAR, M.D.,

PORTLAND, ORE.

AMONG the by-products of "modern" medical methods we find one infant: Spinal Puncture Headache. It is an entirely new thing in pathogenesis and neurology; it differs from all other headaches by coming over the patient in about twenty seconds after he sits up and subsiding in about the same time after he lies down; it begins usually the day following the puncture, when the patient is allowed to sit up; it is throbbing, mostly in the occipital and frontal region, sometimes accompanied by nausea or vomiting; it persists for days or weeks, disappearing often abruptly. The only effective treatment—so far—has been lying down with head low. Charles Dana admits spinal puncture headaches in about one-half his cases; C. With (Copenhagen) in 28 per cent.

Various speculative explanations have been brought forward as "causative" factors of this headache: (1) The rapidity with which the fluid is removed; (2) The amount of fluid withdrawn; (3) The position of the patient during the spinal puncture; (4) The degree of intraspinal pressure at the time of puncture; (5) Whether the fluid is normal or pathological; (6) Whether or not the patient lies flat on his back for twenty-four hours after spinal puncture; (7) Whether or not the amount of fluid withdrawn was replaced by autogenous serum, etc.

Most of these points I regard now as unimportant on account of my observations made in many hundreds of spinal punctures. I followed, for the purpose of comparing results, strictly the following technique: The patient lies on the right side with the cerebrospinal axis as nearly as possible in a position horizontal with the table, the spine well arched by flexing the neck and thighs, approaching knees to chin, the left arm thrown over the head (to widen the vertebral interspace). The needle is then introduced in the midline, between the third and fourth or fourth and fifth lumbar vertebræ (easily found by choosing as point of puncture the interspace just above or below the line connecting both iliac cristæ). As soon as the first drops of fluid appear a rectangularly bent glass tube, thirty centimeters long, with one millimeter bore, and bent at the top, is attached and the pressure is read in millimeters of spinal fluid (water-manometer). As the glass tube holds less than one and one-half centimeters of fluid it is evident that there is hardly any withdrawal of fluid made *before* reading the pressure; each thirteen millimeters of water correspond to one millimeter of mercury. By inclining the tube, the fluid is dropped into the collecting tubes; thus the withdrawal of the fluid is at all times under full control, guided by the effect on the pressure. In my earlier spinal punctures I figured the pressure by counting the drops and noting the force with which the fluid came out of the needle, anything above ten drops per minute indicating an abnormal pressure. Following this technique I could rule out No. 1 "the rapidity with which the fluid was removed" as a possible cause of headaches, because I had full control over the rapidity of flow.

As to No. 2 it made no difference, whether two cubic centimeters were withdrawn or twenty centimeters; I saw fierce headaches follow a withdrawal of four to five centimeters (Cases No. 9, 31, 37, 43, 49, 106), and no headache at all after withdrawing twenty to thirty centimeters (Case No. 102) in patients with nuormal fluids and normal pressure.

Point No. 3, the position of the patient during the puncture, is not valid, because the percentage of headaches reported by authors who punctured the spine in the vertical position is about the same as the percentage obtained in puncturing the spine in the horizontal position.

Point No. 4, degree of intraspinal pressure at the time of puncture; it is claimed that spinal puncture in low pressure is more prone to be followed by headache than spinal puncture in high pressure. I divide my cases into (*a*) normal fluid and (*b*) pathological fluids, and each of these two main groups shall be subdivided—for the sake of argument—into normal pressures (100-150 water), subnormal (20-100), supernormal (above 150). Thus we find in (*a*) group of normal fluids and normal pressure (cases 43, 44, 52, 53, 70) four times headache of two to five days duration; once no headache; in the group of normal fluid with subnormal pressure (cases 32, 34, 42, 45, 47, 48, 49, 51, 76, 90, 106) all followed by headache of two to fourteen days' duration, with the exception of case No. 76, who after the first puncture showed no headache (pressure 80), and after the second puncture (pressure 70) showed three days' headache; in the group of normal fluids and supernormal pressure we find ten cases of headache lasting from four to fourteen days (Nos. 10, 21, 55, 57, 58, 59, 60, 71, 77, 103), one case (No. 59) being remarkable insofar as his previous headaches were relieved by the first spinal puncture (pressure 190) for nine months and when they came on again with intraspinal pressure of 230 millimeters, the puncture was followed by a severe headache of five days duration;

Turning to the (*b*) pathological fluids with normal pressure, we find five cases (Nos. 2, 40, 83, 105, 107), three of which showed no headaches in six spinal punctures performed, while two developed headaches of three to four days' duration respectively; the subnormal pressures of this group are illustrated by case No. 69 with no headache following and case No. 29 with headache of three days following; the supernormal pressures are illustrated by six cases (6, 18, 35, 72, 92, 102) of which three were free of headache, while three developed headache of one to five days' duration. These observations are not in keeping with Landon's statement (*Journal American Medical Association*, May 26, 1917) that he never saw an increased pressure in a purely functional condition, while in organic lesions this complication was nearly always present at some stage. These observations seem to prove further that the intraspinal pressure *per se* at the time of rachicentesis does not play any causative role in spinal puncture headaches; that spinal puncture is less often followed by headaches in luetic fluids than in normal fluids (this answering point No. 5) C. With recorded in 453 spinal punctures on syphilitics 130 headaches, 28 per cent.

*Read at the annual meeting of the American Therapeutic Society, held in Philadelphia, May 7 and 8, 1920.

Point No. 6 is answered by the fact that all my spinal punctures were ambulatory cases, ordered to lie flat on back for 24 hours after their hasty return home; that in spite of this the percentage of headaches following was not larger than in Dana's hospital cases, to wit: out of 94 cases, 47 developed headaches (50 per cent).

As to Point No. 7, many authors—among them Peters—have tried to prevent these headaches by replacing the fluid withdrawn by autogenous serum without finding, however, any lessening in their spinal puncture headaches. One point, not found in the literature on spinal puncture headaches, so far as known to me, seems noteworthy; the influence, which blood oozing into the spinal canal, may have on the production of spinal puncture headaches. Out of eighteen cases in which I collected a bloody fluid, thirteen developed headaches of two to nineteen days duration; this means 72 *per cent of the bloody punctures* showed headache; inasmuch as five of these thirteen cases were syphilitics the fact seemed rather conspicuous in view of the less frequent spinal puncture headaches in syphilitics; as observed above, of the five remaining bloody spinal punctures which did not develop headaches, three were syphilitics. From these data I conclude that blood oozing into the spinal canal may have some influence on the production of headaches.

The one feasible explanation for these headaches, seems to be Sicard's (Paris) view, who found that the rigid dura does not close under thirty hours and generally requires from thirty-four to thirty-six hours; MacRobert (*Journal American Medical Association*, May 11, 1918) became "convinced that closure of the puncture hole usually takes place in the following way: the arachnoid tissue, as it drops from the point of the departing needle, is swept snugly against the dura mater, by the pressure of fluid within. In this way the dural hole is blocked by an intact area of the arachnoid membrane, as the puncture holes, being small, are unlikely to approximate. If the puncture hole is not blocked, it is because the delicate arachnoid tissue clings around the departing needle, and its hole is pulled into and through the hole in the dura. There it impinges, and this invagination forms a spout or wick for the easy drainage of the whole cerebrospinal sac, and also prevents the rapid healing, which would otherwise occur, of so small a dural opening. *It is the continuous epidural leakage of cerebrospinal fluid through a patent puncture hole, that takes away the water pad of the brain,* so that the brain rests unprotected on the irregular bony surface of the base of the skull, causing an irritation of the dural fibers of the fifth and occipital nerves. The fact of the instant relief caused by the horizontal position supports this view.

In the course of treating my neurosyphilis cases I made it a routine practise to tap their spinal canal for reasons of prognosis. I noticed that the cases in which I tapped more frequently made better clinical and laboratory showing, so I concluded, that perhaps the systematic tapping of the cerebrospinal canal, immediately before injecting the salvarsan (which I always used in dilutions of at least 0.1:40) might be beneficial to these patients, by quasi drawing the salvarsan from the blood stream into the spinal canal. While Mehrtens (*Archives Neurology and Psychiatry*, October, 1919) did not find arsenic in the spinal fluid following this method in five cases, my clinical findings, the Wassermann, cell count, etc., in the spinal fluid, after such procedure, encouraged me to continue this line of treatment. It simultaneously became very apparent to me, that a large majority of the cases thus treated, only rarely developed spinal puncture headaches, most of them following their usual occupation next day. This fact suggested to me, to follow up *every* spinal puncture immediately with intravenous salt solution, if not giving simultaneously salvarsan. The results were rather conspicuous:

Number of *headaches without salt solution*:
93 cases; 51 headaches.....55 per cent
(Non-syphilitics, 66 cases, 44 headaches .....66 per cent)
(Syphilitics, 27 cases, 7 headaches .....26 per cent)
Number of *headaches with salt solution*:
50 spinal punctures (17 cases) 3 headaches .....6 per cent
(Non-syphilitics, 7 cases, 1 headache .....14 per cent)
(Syphilitics, 43 spinal punctures (10 cases), 2 headaches ..... 5 per cent)

An entire change as to spinal puncture headaches! The prophylactic value of these intravenous injections of 0.5 per cent NaCl 500 to 750 c.c., may also be gleaned from the fact, that cases 6, 25, 66, 105 when spinal puncture was done without being followed by 0.5 per cent NaCl, suffered from headaches for two to sixty days, while *if followed immediately by the salt solution these same cases* developed *no headaches*.

The objection may be raised, that the mentioned cases probably might not have developed headaches anyway, being syphilitics. These skeptics I would direct to the above figures on non-syphilitic spinal puncture headaches following prophylactic injection of 0.5 per cent NaCl solution. Out of seven spinal punctures on non-syphilitics (Cases 14, 22, 26, 66, 78, 108, 109) only one developed headache; that is 14 per cent—not 66 per cent as was my previous experience in many hundreds of non-syphilitic cases.

Stevens Building.

THE UNCONSCIOUS.

By H. Laveson, M.D.,
New York.

By unconscious I mean any one of the innumerable motions of and in the body, of which we are generally unconscious, including those of which we sometimes do become aware, the typical instance of which, within the body, is the circulation of the blood. From time to time we do become conscious of the heartbeat and we know how certain kinds of thoughts will cause it to become more rapid. It is also conceivable how certain kinds of thoughts would cause the calibre of the blood vessels to change in different parts of the body, thus lessening or increasing the amount of blood delivered there, and how in the same way other fluids closely connected with the most fundamental physiological

processes might be affected. Conscious action includes voluntary action and involuntary movements of which we get a sensational report through the afferent nerves. The causes of voluntary action may be supposed to be the thoughts which precede and accompany it. The causes of involuntary movements have hitherto been presumed to be movements and not thoughts, that is, movements in the tissues of the body. But it seems quite certain that when movements become small enough they are indistinguishable conceptually from thoughts, which we must therefore include as among the causes of the involuntary muscular movements, as well as of the movements involved in the various physiological functions. So that we can see here the possibility of the involuntary movements being caused by unconscious thoughts, and we get an idea of how logically necessary is the concept of an unconscious thought, and what may be the nature of an unconscious thought, namely, a movement which is so slight that it has not the force to penetrate into consciousness, or, figuratively speaking, the position whence it could pass over into or be read off as conscious thought. And we see, finally, that the only difference between a conscious thought and an unconscious thought is just this fact of its being in consciousness, its being cognized, our being aware of it. There is no other difference whatever.

The distinction between the unconscious and the foreconscious is that the former contains all the memories which cannot come to consciousness, and there are a great many of them, while the foreconscious contains the memories of all kinds which can be voluntarily evoked from time to time. Between this freely coming and going group of ideas which, like familiar names, dates, telephone numbers, scraps of poetry, music, etc., and the vast body of totally unconscious memories, accumulated certainly during the lifetime of the individual and possibly during the life of the race, there is a barrier over which the truly unconscious mental activities are absolutely unable to pass. We know of their existence by inference only, but by an inference which is so logical and free from fallacy that it is impossible for those to doubt it who have taken the trouble to sift the evidence. Not only of the existence of this unconscious, the thoughts of our minds, irrecoverable, without the special technique of psychoanalysis but of its nature we have some reliable information. It exists as a blind wish, an amorphous craving which can best be described as an unreasoning urge to life and love. The illimitable power of this desire, expressing itself, among other ways, in minute muscular contractions in all parts of the body, is normally able to transcend the barrier above mentioned only in the form of actions which are approved by society. Certain disguises are adopted by the utterly unconscious wish, which convert it into specific foreconscious wishes with a definite form, and, bearing these disguises, it comes now and then into full consciousness. The group of disguises, much like the costumes of the actors in a play, and like the words, intonations, and movements which are prescribed by the author and the stage manager, are ready in the wings of the foreconscious to appear in the drama of consciousness. And as the author will not write, or the stage manager produce, what will not appeal to the public, so the guardian called the "Censor" at the barrier above mentioned will not allow any unconscious wish to appear, except those disguised so as to be acceptable to society.

Thus is to be represented the condition of thoughts which exist in the permanently unconscious and in the temporarily unconscious state called the foreconscious. I regard as unconscious acts both those of which we never become aware, such as the movement of muscles and fluids accompanying the physiological functions which never enter consciousness as such, and the movements of the parts of the body of which we only sometimes become conscious. Some of these are called symptomatic acts from their analogy with the symptoms of certain nervous diseases, although, as they occur in all persons, well or ill, there is no present implication of abnormality in them. They are all blunders, errors, slips of the tongue or pen, mannerisms, and even some forms of so-called neuralgia, twitching of the face, etc.

As the development of human society has been such as to give in all ages and places a greater value to the performance of other acts than the instinctive act of procreation, there has sprung up universally a resistance against mere reproducing and eating. It has been universally felt that a race devoted to those two aims solely is not different from animals of lower orders in whom there is no other activity worthy of the name. But wherever the resistance against the mere following of the passions called animal has come from, it exists and has been the cause of all the strictly human phases of human life. We are not concerned here with the origin of this difference between animals and man. Here we have to do only with the fact of it and the way it is accomplished by the conscious mind. There are not plenty of conscious resistances against crass sexuality. In fact, the resistances against a purely animal life are those of consciousness primarily. The barrier set against purely animal thoughts, which continually strive to come into consciousness both in thoughts and in acts without thoughts, has been fitly compared to a Censor who examines communications between people and deletes matter which is considered unsuitable for communication. So it is customary to say that the thoughts-wishes of the unconscious which are solely concerned with material sustenance are censored. And in order to pass the Censor they are disguised or cloaked.

Identification.—The mechanism called Identification, based on similarity, is an unconscious mental process which underlies a great deal of conscious thinking and acting. One identifies oneself with other persons and things in such a way that those persons or things are regarded as a part of oneself. Indeed it is, when we consider it closely, a difficult problem to decide where the average person conceives his ego to end and the external world to begin. Physically our digestion identifies our food with our bodies literally. Mentally we regard certain parts of ourselves as more intimately ourselves than other parts. For example, the attached parts of our finger nails are more closely a part of us than are the unattached parts which we cut off from time to time, and our hair is not so

intimately a part of ourselves as our eyelashes. Furthermore, some of our passions we identify with ourselves much more than we do others. From our earliest years we identify ourselves with persons. In our desires, both conscious and unconscious, we identify ourselves on the one hand with our fathers and on the other with our mothers. Later there is a perfectly normal identification in the love we feel toward our life partners. A curious and important fact not generally known is that when at a later date we have ceased to identify ourselves with our parents as they are at present, we still retain in the Unconscious the original identification which we formed at an early date with the parent as he or she then was.

The Unconscious Wish.—The aspect of the Unconscious which influences the physical health of the individual, as well as his mental health, is the Unconscious wish. It has been shown by the newer psychology that the Unconscious wish is a tension which is expressed only through the muscles, not only the larger and more familiar ones but also the very small ones of which we are never conscious. These small ones contract and expand with the result of enlarging and diminishing the calibre of the passages in the body through which go air, food, blood, and various other fluids, and therefore govern the development of those parts of the physical organism which are supplied by the various chemical products of food, air, and water.

These wishes or tensions or infinitesimal inceptive movements of the muscles are at once too small to enter our conscious life and yet so numerous and so powerful as to influence it greatly, though in ways that appear to be extremely indirect. They are, in their gross effects, distantly comparable with the rising or falling of the tide in a river which lifts a vessel alongside of a wharf, imperceptible to the eye while the eye has the patience to keep looking, and yet causing a change which is noticeable from time to time as one observes the height of the vessel against the wharf.

The wishes or tensions which exist unconsciously in the mind of every person when confronted with a hard task of any nature whatsoever correspond, in this comparison, to the limitless force of the uplift of the water on the hull of the vessel, and the conscious attitude of the individual corresponds to the physical effort which a boy or a girl might exert to oppose or assist in the upward movement of the boat on a rising tide. The effect on the boat is virtually nothing, while the effect on the boy or girl is directly in proportion to the effort put forth. Very wise are they if they cease exerting themselves as soon as they have stirred up a vigorous circulation.

The Unconscious is one continued wish or tension or bundle of tensions. These tensions are relaxed or resolved naturally from time to time in the act of creating or the act of eating. I use the word creating instead of reproduction, for the reason that the two main forms of the desire perpetuation are the perpetuation of self, and, as a variety of self-perpetuation, that of the race. Now, the race-perpetuation instinct, like all instincts springing from it, is transmutable. It may be transmuted from one kind of creation to another. This transformation of the creative instinct from physical reproduction of species to production or creation of other things which has always been spoken of as higher, is called by the aspiring name of Sublimation. And it is really higher from the point of view of personal power and accomplishment. For the difficulties overcome in accomplishing it, which measure the value of it as a conscious production, are much greater than in the reproduction of kind, in which one acts spontaneously, without resistance, and without sense of personal achievement or with only an illusory one. What nature causes and completes is so separate from the Ego, that opposes and overcomes that nature in us, that our overcoming it seems much more our own doing than anything in which nature wholly concurs. Thus it is evident that the accomplishment most gratifying to the individual consciousness is that which most overcomes, masters, or controls the instinctive and unconscious tendencies. In yielding to and falling in with the instincts, which are absolutely common and universal, we are not developing that power which most typifies our existence as individuals. In doing the most common things we are surrendering our separateness as individuals and sinking ourselves into a larger organism—the race.

Fear is unconsciously determined. Fear is really at bottom unconscious desire. A conscious fear of being unable to do a certain act is really an unconscious desire to do it, and a state of mind in which fear is specially predominant, such as a phobia is one where there is a strong desire (in the phobia fundamentally sexual) which is being unsatisfied.

The unconscious tensions or wishes of the human individual are from minute to minute relaxed and tensed. This rhythm of tension or wish and relaxation or gratification goes on from moment to moment in the mental life of each one of us. It is going on with the regularity, if not with the rapidity, of the heartbeat. If every human wish is fulfilled in some way it is quite evident that if it is not consciously fulfilled it must be unconsciously. The unconscious of each and every individual is an unlimited store of material for wish fulfillment. The very act of relaxation, even that coming through fatigue, is a fulfillment of a wish in so far as it is the relaxation of a tension. And as the tension will relax, even though the intended gratification is not actually secured, we find ourselves, possessed as we are with a faculty of mental reproduction of sensations, deriving our satisfactions from ideal, imaginary internal sources, instead of the external ones which have disappointed us. The unconscious craving always tends outward, but its natural extraversion is for the purpose of getting its own internal satisfactions. It may be said that a noticeably strong conscious tendency in any direction is likely to indicate the presence of an opposite tendency in the unconscious, much as a convexity on one side of a thin metal plate corresponds to a concavity on the other side. And in each case it is really the same force which produces the unevenness. Any unevenness in character or idiosyncrasy or eccentricity is thus seen to be the work of unconscious forces, the conscious form in which they are displayed almost invariably being a displacement of some sort.

A compensation is a conscious effect of an unconscious cause. Only one member of the analogy

enters consciousness while ambivalence keeps both members of the equation, both sides of the balance, so to speak, below the threshold of consciousness. It is only in the mechanism of compensation that one of the pair of activities appears in consciousness. A person will compensate with conscious actions for an unconscious desire, just as he will balance two conscious desires and throw more impetus into the one because it is a socially approved one, for the reason that he has already thrown more than he thinks he ought into the other, and he wishes to keep a certain balance between what he instinctively wants to do and what, from his experience of society, he thinks it wants him to do. By keeping an even balance in this way he satisfies his conscience and does not worry. A corollary of this compensating for an unconscious desire by means of a conscious one is that we have no conscious desires that are not compensations. It is quite evident that as the unconscious desires are the pressure of the animal instincts, against which society has set up numerous barriers, we should, if we followed these all the time, do practically nothing of all the complicated web of human activities which now we are weaving.

Subconscious and Unconscious Ideas.—There is a school which regards the subconscious as formed of "suppressed mental complexes." The views of this school are not psychologically clear. It seems, however, that the subconscious is viewed in the light of "unconscious ideas." The German school, with Wundt at its head, at first started out on similar lines, but they could not make any use of the subconscious, and their speculations ran wild in the fancies of Hartmann. The reason of this failure is due to the fact that the concept of the subconscious as conceived by the German school was extremely vague, and had rather the character of a mechanical than that of a psychical process. An unconscious consciousness—that was their concept of the subconscious. In such a form as this the subconscious was certainly meaningless—mere nonsense—and had to be given up. The German psychological investigations are now confined to the content of consciousness in so far as the individual is immediately conscious of it. But as this form of consciousness is extremely narrow and circumscribed, the results arrived at, though remarkable for their thoroughness, are, after all, of a rather trivial nature. It is what James aptly characterizes as "the elaboration of the obvious."

This criticism applies well to Freud and his adherents. "Das Unbewusste" is conceived as "Suppressed unconscious idea-complexes." Of course, the claims of that school to originality and to the apparent unveiling of the causation of psychoneurosis are entirely unjustified. A "suppressed complex" is but another term for a dissociated system, commonly accepted in psychopathology. The special theories developed by that school in regard to desire, to sexuality, and to voluntary suppression of unpleasant or painful ideas are entirely gratuitous and false in the light of modern psychology and clinical experience.

This psychoanalytic school has unfortunately fallen back on the Herbartian psychology with its metaphysical Reals or ideas which by their mutual tension keep suppressing one another, thus determining the display of the contents of consciousness. As Herbart tells us: "Concepts become forces when they resist one another. This resistance occurs when two or more opposed concepts encounter one another." This proposition or principle proclaimed by Herbart is at the basis of Freud's mythical speculations. "A concept is in consciousness in so far as it is not suppressed," Herbart tells us, "but is in actual representation. When it rises out of complete suppression, it enters into consciousness." According to Herbart and his modern followers, suppressed ideas become forces and impulses. Concepts which are not opposed or contrasted with one another, so far as they meet unhindered, form a "complex," a favorite term used by the psychoanalytic school and its followers.

It may possibly be of interest to remark that Herbart is closely followed by the psychoanalytic school in regard to the doctrine of desire. Desire with Herbart is fundamental: "The faculty of desire must include wishes, instincts, and every species of longing." "The expression 'desire' must not be so limited as to exclude those wishes which remain, though they may be vain, or so-called pious wishes, and which, for the very reason that they do remain, constantly incite men to new efforts, because through them the thought of a possibility is ever anew suggested, in spite of all reasons which appear to prove the impossibility of attainment. It is very important to give the concept of the unattainability of the wished-for object, strength enough so that a peaceful renunciation may take place of the desire. A man dreams of a desirable future for himself, even when he knows it will never come." These Herbartian doctrines, long ago abandoned by psychology, are now being revived by the marvellous "scientific" psychoanalytic technique as a new discovery in the science of normal and abnormal psychology. No better criticism can be passed on this revival of Herbartian psychology in the domain of psychopathology than the one made by James: "I must confess that to my mind there is something almost hideous in the glib Herbartian jargon about Vorstellungmassen and their Hemmungen (suppressions) and sinken and erheben and schweben and Vershmelzungen and Complexionen (complexes)."

It is claimed by some of Freud's younger adherents that the mechanism of "unconscious ideas," though a contradiction, is nevertheless justified, because of its being a conceptual construct, as Karl Pearson puts it, in order to aid the explanation of mental phenomena. This is a new epistemological argument in defence of a tottering system. It is truly amazing that science has nowadays become so philosophical that when a theory is unstable, it is unhesitatingly supported by epistemological considerations.

Perhaps it may be well to point out that self-contradictory hypotheses are not quite acceptable in science. In other words, the hypothetical causative agency must be conceived in terms of experience.

The hypothetical agency must either be a fact directly observed in nature, or a fact which can be verified later on. Thus the theory of gravitation is based on the facts of falling bodies; the theory of natural selection is based on the facts of the struggle for existence observed in the organic world. In

short, a good scientific hypothesis must take as its causative agency a *vera causa*, a fact observable in experience, or a fact which can be verified by further experience. Atoms, electrons, ether, are not haphazard constructs; they are not regarded by the physicist as unreal fancies, unreal abstract notions to explain the real facts; but each of these hypothetical agents is regarded as real, as a *vera causa*. We cannot help agreeing with J. S. Mill on the subject of hypothesis related to causation, that the supposed cause should not only be a real phenomenon, something actually existing in nature, but should be already known to exercise, or at least to be capable of exercising, an influence of some sort over the effect. In any other case it is no sufficient evidence of the truth of the hypothesis that we are able to deduce the real phenomenon from it. Again, What is true in (Newton's) maxim is that the cause, though not known previously, should be capable of being known thereafter; that its existence should be capable of being detected, and its connection with the effect ascribed to it should be susceptible of being proved by independent evidence.

If we apply this very simple rule of logic to the theory of "unconscious ideas," we at once realize the illegitimate character of such an hypothesis. An idea is essentially of a conscious nature. To speak, therefore, of unconscious ideas, is to introduce into psychology the self-contradictory, impossible concept of unconscious conscious ideas. This is equivalent to the assumption of an unconscious consciousness. An unconscious idea is neither a *vera causa* nor a fact ultimately to be verified. The conception of an unconscious idea is like the conception of a round square.

Moreover, it is not true, psychologically, that ideas can be "suppressed" so that they become dissociated or "unconscious." It is not true that we suppress painful ideas into the "Unconscious." We do not forget our painful ideas. On the contrary, painful ideas stand out all the more prominent in our consciousness. Pain hammers experience into the mind. In fact, we may say with more right that it is the pleasurable ideas that are forgotten, while the painful ideas are remembered. An experience associated with pain is never forgotten. Like a splinter in the flesh, it remains in consciousness. It is due to other causes that a painful experience becomes subconscious.

Teleologically, we can well see the importance of this fact. It would have been suicidal to the individual and ultimately to the species, if painful experiences were forgotten. The individual must learn to avoid harmful objects and hurtful stimuli. This can only be accomplished by actually remembering painful experiences. That individual would survive who remembered best his painful experiences. Were it otherwise, the individual would be very much in the condition of the proverbial silly bird that hides its head at the sight of the hunter. The subjective painful experiences must be remembered; a painful experience fixes the attention.

On this fact of strengthening memory by pain was based the once universally recognized method of training and education. What is fixed by pain is never forgotten. What may bring about forgetfulness is either a constitutionally bad memory, or a state of indifference, or an intense, paralyzing emotion of fear, especially in early childhood. The whole theory of "suppression" of painful "complexes" is based on false clinical and psychological assumptions. Neither is there such a process as "suppression of complexes," nor is there such a mental state as an "unconscious idea."

Bergson, who as usual has his hand everywhere, takes up cudgels in defense of the unconscious. In his work "Matter and Memory" he argues that common sense assumes the presence of external objects, although it may not be directly cognizant of them. Being an idealist and pan-psychist, Bergson regards the nature of things as made up of images. If, then, he reasons, common sense believes in the existence of objects "passed out of sight and sense," if it affirms unhesitatingly the actual existence of not directly experienced objective images, there should be no difficulty in assuming the existence of subjective images, or of psychic states of which there is no consciousness. The argument is essentially metaphysical and will hardly have any weight with the psychologist or psychopathologist.

Bergson's psychology is unfortunately so much saturated with metaphysics that many a valuable suggestion becomes lost in the haze and tangle of his speculations. The psychologist has nothing to do with the constitution of matter as it is in itself. This belongs to metaphysical ontology. The psychologist assumes matter as an external existence, and separates it from his own subject matter,—psychic states, mental processes, their elements and relations. A psychic state made up of "images" after the fashion of "material images" with no consciousness to them ceases to be psychic in the psychological sense. From a psychological standpoint the term psychic can only mean some form of consciousness, however vague and marginal. Bergson's view would have probably been nearer the truth if he had assumed the existence of a subconscious consciousness.

An "unconscious idea," in the sense that the idea has no consciousness, can have no meaning. If, however, by an "unconscious idea" is understood a consciousness of which the individual or personal self is not conscious, then we come around to a subconscious consciousness, as developed by me in my various works. A quotation from Höffding may bring out my point in a clearer and stronger light: "The question before us is, whether the unconscious can be other than a purely negative concept. In daily speech we use such expressions as unconscious sensations, unconscious ideas, unconscious feeling. As, however, sensations, ideas, and feelings are conscious elements, the expression is in reality absurd. If by an unconscious idea is meant the idea which I have, then the predicate "unconscious" signifies only that I do not think of or pay heed to the fact that I have it. This use of the word unconsciousness is connected with a twofold use of the word consciousness. It is used to denote not only the inner presentation of our sensations, ideas, and feelings, but also self-consciousness, the attention especially directed to our sensations, ideas, and feelings. We have, of course, many sensations and ideas without being conscious that we have them, that is, without self-consciousness; many feelings and impulses stir within us, without our clearly appre-

hending their nature and direction. In this sense we speak, for example, of unconscious love. A man who has this feeling does not know what is astir in him; perhaps others see it, or he himself gradually discovers it; but he has the feeling, his conscious life is determined in a particular way."

In other words, what Höffding practically claims here is that there is no such mental state, no idea that is "unconscious," but that there are mental states, ideas, feelings, which, though conscious, do not reach self-consciousness. In other words, there are in us mental processes which have consciousness, but no self-consciousness. This is precisely what I mean by the subconscious—mental states which have consciousness, but do not reach the personal consciousness. In short, the only possible psychological assumption is a subconscious conciousness.

The Subconscious, Conscious, and Unconscious.—Those who accept the division of the subconscious into coexisting consciousness, or the co-conscious and the unconscious really assume the doctrine of the subconscious. They claim that it would be better and more precise to indicate, whenever possible, the conscious or unconscious, that is, the strictly physiological character of the observed manifestations. This, however, is more easily said than done. We know next to nothing of the physiological brain processes which are mainly hypothetical, and we do not know the limits of the subconscious consciousness. In many cases it is not easy to determine what the exact character of the subconscious manifestation is, how far it is conscious, dimly conscious, how far it has gone toward the development of an independent personality, and how far it shades in the direction of the purely physiological. In the absence of any exact determination, the term subconscious indicates the character of the mental state without any definite committal to any of the possible hypotheses.

The term "unconscious" is all the more objectionable, as Höffding has already pointed out, it is essentially an ambiguous, negative concept. The "unconscious" may mean absence of self-consciousness, or lack of consciousness, that is, purely physiological processes with no conscious concomitant. He who uses the term "unconscious" must in each case indicate in what sense he uses the term. Is the manifestation entirely physiological, or is it conscious in the sense of consciousness with no self-consciousness? The two meanings are diametrically opposed to each other. The unconscious in the sense of the purely physiological assumes the theory of unconscious cerebration; the other use of the unconscious in the sense of mere consciousness with no self-consciousness recognizes the view of the subconsciousness as advanced elsewhere.

It is claimed again that in many cases of psychopathic maladies there is no need to have recourse to subconscious systems. It is quite probable that the association between the stimulus and the emotion called forth is a direct one. The patient who is afraid of dogs has the fear called forth by the sight of a dog. There is no need to assume that there are here any intermediate links in the chain of association. Even physiological links may be totally absent here. It may be that by investigation it can be shown that this association has a history based on some former experience. There is no reason to assume that the experience is functioning subconsciously, whether consciously or "unconsciously," that is, physiologically. The dog and the fear have formed an indissoluble association, so that, as soon as the dog is perceived the fear is awakened.

This, however, is rather a debatable subject, since it is impossible to tell in the case of purely physiological links whether such are present or not. Thus, Höffding says, "Not only may conscious results come from unconscious working up, but there may also be unconscious intermediate links in the midst of conscious work. Supposing the idea *a* to be linked with the idea *b*, and *b* again with *c*, then *a* will finally produce *c* directly without the intervention of *b*. The intermediate links are often so numerous that they cannot be recovered at all or with great difficulty. Many psychological paradoxes and sudden suggestions have their explanation in this unconscious determining of conscious ideas."

Wundt seems to maintain the same view: "The memory process is especially predominant in those cases where the element of the new impression that gave rise to the assimilation is entirely suppressed by the other components of the image, so that the associative relation between the memory-idea and the impression may remain completely unnoticed. Such cases have been spoken of as 'mediate memories' or 'mediate associations.' Still, just as with 'mediate recognitions,' we are here, too, dealing with processes that are fundamentally the same as ordinary associations. Take, for example, the case of a person who, sitting in his room at evening, suddenly remembers, without any apparent reason, a landscape that he passed through many years before; examination shows that there happened to be in the room a fragrant flower which he saw for the first time in the landscape. The difference between this and an ordinary memory-process in which the connection of the new impression with an earlier experience is clearly recognized, obviously consisted in the fact that here the elements which recall the idea are pushed into the obscure background of consciousness. The not infrequent experience, commonly known as the 'spontaneous rise' of ideas, in which a memory-image suddenly appears in our mind without any assignable cause, is in all probability reducible in every case to such latent association." It appears, then, that both Höffding and Wundt acknowledge the presence of intermediate links in what appears to be a case of purely "immediate" association.

In cases where the intermediate links are "unconscious," in the sense of a purely physiological process, there is no criterion to prove the presence of such intermediate physiological links, and one may as well, from a purely psychological introspective standpoint, deny their very existence. On the other hand, if with Wundt, Höffding, and others we assume the presence of intermediate psychic links, there is no way of disproving them. It is quite probable that such intermediate links are present in every single case. The very fact that "unconscious" systems can be revived as memories or hallucinatory hypnoidic states would indicate their functioning when one of their components becomes awakened to activity.

As an objection to the presence of intermediate psychic links Pavlov's experiments are brought forward to show that associations can be formed between remote stimuli and glandular secretions, for instance. Thus, a dog with a fistula in the parotid gland can be made to react with secretions to light or sound stimuli.

This objection may be easily obviated by the consideration that we do not know whether there are or are not intermediate mental links between the artificial stimuli and the discharge of the glandular secretion. This consideration is all the more cogent as the remote stimuli can give results only if persistently associated with food stimuli. If such association with food stimuli is absent, and new stimuli are associated with remote stimuli which give reactions through their associations with food stimuli, the result of inhibition of secretion. In other words, each new stimulus must be directly associated with the original food stimulus.

To quote from Savadsky's work carried out in Pavlov's laboratory: Wasiliev and Mishtoot were the first to investigate conditions of inhibitions. At first the authors had in mind to develop conditional reflexes, not on the basis of another conditional reflex (such as a sound or light stimulus giving secretion). Their experiments were as follows: "From time to time they associated with the usual conditional stimulus another stimulus which had no relation whatever to salivary secretion, and this combination was not accompanied by the presence of the unconditional stimulus (food). By means of a great number of repetitions of such a combination, it was supposed to associate with the quality of the extraneous stimulus the quality of bringing about salivary secretion. It turned out, however, that such an arrangement of experimentation could by no means transform the extraneous agent into a conditional stimulus. In that way it became clear that the conditional stimulus, contrary to the unconditional, is not capable of communicating its property of bringing about salivary secretion. The fact is that the associative external stimulus, when accompanied by the unconditional stimulus alone, becomes after a few repetitions a powerful inhibiting agent."

This clearly shows that the conditional reflex in the dog can bring about salivary secretions only when associated with the unconditional reflex. What it means is, that the dog on seeing a *light* or hearing the *sound* expects food, and hence the psychic stimulation of his salivary glands resulting in secretion. Pavlov's experiments and also the experiments carried under his direction by his pupils clearly prove that there is no direct association between secretion and an external stimulus such as light or sound, but that the secretion is brought about by an intermediate psychic link, namely, the expectation of food. Thus we find that the work of Pavlov and his pupils, far from showing the possibility of formation of direct associations, really goes to substantiate the view of the presence of intermediate mental links in cases of apparently immediate associations.

As a matter of fact, there is no need for us to establish hypothetical, intermediate, unconscious, or physiological links. The "unconscious" brain-processes are problematic entities and there is no way of getting at them. What we need to discover in cases of mediate association, and especially in cases of psychopathic diseases, is whether the intermediate links, or the state of dissociation is present, consciously, or subconsciously, or co-consciously. This is possible to test by hypnosis or by means of the hypnoidal state. In many such cases we actually find that the patient lives through the original experience either consciously in a hypnoidal state, or in a hypnoidic state, thus undergoing a mental experience which is more commonly the case, the patient lives through the original experience subconsciously. But, whether conscious or subconscious, the mental state is not "unconscious," but is essentially of a conscious character. In short, we deal here either with the personal consciousness or with the subconscious consciousness. Thus, all the facts of mental life, normal or abnormal, substantiate the presence of a subconscious consciousness.

ETIOLOGICAL CLASSIFICATION OF HEART DISEASE.*

By CHARLES M. NICE, M.D.,

PHYSICIAN-IN-CHIEF, BIRMINGHAM INFIRMARY, INTERNIST HILLMAN HOSPITAL,

AND

J. G. VANCE, M.D.,

PHYSICIAN TO THE BIRMINGHAM INFIRMARY, BIRMINGHAM, ALABAMA.

THERE are few rules in medicine that are not subject to more or less elasticity of interpretation and still fewer classifications of diseases that meet all requirements. In diseases of the heart it is necessary, as the groundwork, that every student have a thorough knowledge of the location and pathology of the various lesions. In the treatment, the symptoms and the history must be seriously considered for effective results, else the knowledge of the location may go for little practical importance, since the application for a similar point in one patient may vary greatly from another. The variance may be just as great in the pathology.

The heart has so many close associations that disease in any other organ may markedly interfere with the cardiac function. Under such circumstances, it is often well-nigh impossible from a practical standpoint to separate the primary offender. For instance, in cardiorenal disease, it is very difficult in the majority of instances to make this distinction. However, in all heart affections, whatever the cause, the association of a coexisting renal disease is so common, both in the early and especially in the later periods, that it is customary to think of them conjointly. Treatment is therefore instituted along similar lines with a formulated opinion but often without positive knowledge of the primary affection.

Since the advent of focal infections internists have become students of the origin of many diseases that previously were considered only from a geographical or picturesque standpoint, consequently our therapeutic efficiency has grown with much

*Read before the Annual Meeting of the Chattahoochie Valley Medical Association, July 13, 1920.

vigor. We no longer think of fever and high blood-pressure except in symptomatic terms.

No doubt most of you have selected for your individual selves a method of thought for the classification of heart diseases as well as conditions arising in other organs. Some think of the right heart for one thing and the left for another group, but how little is the importance of really locating the actual valve, from a practical standpoint, unless we consider and know the etiology? Perhaps for the listing of a card index or the signing of a post certificate the old classifications are required. It is taken for granted, however, that everyone should be just as exacting as formerly in his physical examination and history taking, both of which occupy the strongest field in diagnosis.

From the standpoint of relative frequency, importance and limited conciseness, the various forms of pericardial, myocardial, and endocardial, including cardiac neurosis, may be classed under five main groups. Many other heart affections not minutely mentioned in this paper may be made to fit into one of these heads. It is taken for granted that all cardiac diseases, excepting congenital, begin as acute conditions and later become chronic in the gross meaning of the word, unless interrupted in one or another stage. Some, of course, are primary, others secondary, when considered with relationship to other organs.

Group No. 1. *Acute infectious heart disease, later becoming chronic.*—Under this heading have been placed the various muscular and valvular inflammations arising during the course and following such diseases as rheumatism, tonsillitis, chorea, influenza, scarlet fever, typhoid, pneumonia, diphtheria and focal infections. The chief offender in this type is the streptococcus, which represents by far the majority of cardiac affections. The preliminary history is readily obtainable and the physical signs vary with the location whether it be in the pericardium as an adhesive percarditis or in the valve as a murmur. This form often is associated with a fever, usually of a mild degree, malaise, myalgias and arthralgias, rigors and anorexia. It is the most common of the heart diseases of children and youths and the largest contributing cause of chronic lesions.

Group No. 2. *Syphilitic Heart Disease.*—This, perhaps, should be accorded second place in frequency, especially when considered in relationship to middle life, and anatomically, to the aortic valve. Pathologic findings are most common in the muscular wall and the valve mentioned. The nervous manifestations of this type without physical findings will also be mentioned in another group. The presence of an aneurysm, the history and a positive Wassermann from the blood or spinal fluid, give the evidence necessary for the classification. The symptoms are in accord with the degree of damage done or being done.

Group No. 3. *Renal-Arteriosclerotic Type of Heart Disease.*—In this group the associated kidney disease is predominant. Senile and premature sclerosis of the blood vessels and heart proper are found. As previously stated, the definite separation of the heart and kidney from a causative reasoning is often impossible. The symptoms of this large class of cases vary. Continuous or paroxysmal dyspnea, pallor, headaches, dizziness, precordial pain, disturbances in the quantity of urine, edema and effusions, gastrointestinal disturbances, languor, coma, cerebral symptoms and hypertension are those chiefly encountered. The physical findings are distributed to all parts of the body. There may be murmurs with changes in the heart boundaries and accentuations of sound. There are urinary findings always of importance. Changes in the eye-grounds and in the functionary kidney tests are noteworthy. This type affords the end-process of many lives, and a thorough study of each case separately will clarify the numerous lines for therapeutic procedure.

Group No. 4. *Neuro-Toxic Heart Diseases.*—The etiological consideration of the factors arising in this group includes the glandular affections such as goitre and menopause, and concomitant causes such as uterine fibroids; neurasthenia and the poisons, as alcohol, tobacco, and opium. Syphilis without physical findings is responsible for many of these conditions, which are brought about by its effect on the nervous system directly or indirectly, caused by the spirochete; by the treatment given for the disease, or by a type of neurosis caused in sensitive patients. Gout, diabetes, tuberculosis, malnutrition, and gastrointestinal conditions, either through pressure from flatulence or toxicity through malabsorption, are responsible for a large share. Neurotic conditions in young girls and boys, and shock in war give rise to many other of the nervous types of heart disease. The symptomatology of these cases is often lacking, but the symptoms are related chiefly to the hypotension type, to bradycardia and tachycardia, and arrhythmias, and a great variety of symptoms are found in the various forms.

Group No. 5. *Congenital and Anatomical Heart Disease.*—Finally, a small number of heart conditions may be seen under the title of congenital and anatomical heart disease. This will include a patulous foramen ovale, valvular defects, anomalies in size of the different cavities, and deformities of the chest and spine. Increased adiposity or obesity of the heart are also included. The pathology and symptoms are very variable, depending upon the condition present. The large majority of this group occur in infants and children whose survival is determined by a short number of years. The adipose variety have symptoms from the mildest to the most grave, but, without concurrent disease, appear to live an uncomfortable but shortened existence.

It is understood that the hypertrophies, dilatations and effusions are largely mechanical, and their results may be noted in any of the above groups, but they are always secondary in nature.

With this classification it would appear much easier to think of and study heart diseases, and certainly our practical therapeusis and prognosis will grow less and less difficult as our knowledge of the underlying causes increases.

525 Woodward Building.

A New Treatment of Metasyphilis.—The idea of treating paresis with cultures of protozoa and spirilla, with infected blood, etc., is being tested in Germany. The spirochete of recurrent fever and one recovered from a species of African rat are specifically named, as is virulent malarial blood. No permanent benefit seems to have been reached.—*El Siglo Medico.*

PROTEIN SHOCK REACTION IN LEPROSY.

By EMANUEL M. JOSEPHSON, M.D.,

NEW YORK.

I HAVE had occasion to observe a protein shock reaction in a leper, and deem the observation of sufficient interest to report it. An unknown amount of a vaccine was accidentally administered with an intravenous dose of sodium gynocardate to a patient suffering from a quiescent but well advanced leprosy. A typical protein shock reaction followed shortly after the injection. For several days following the recovery from the shock the patient stated that he felt an improvement, notably in several anesthetic areas. Within a week, however, there supervened a marked exacerbation of the disease. A crop of maĉules rapidly appeared, more markedly over the parts previously more extensively involved, the face and the arms; a chronic ulnar neuritis lighted up and once again became hyperacute, and the patient ran a low fever as compared with his previously subnormal temperature. When I last saw the patient two months later, the exacerbation had not yet subsided.

This case indicates that the protein shock reaction has some possibilities in the diagnosis of latent leprosy. The reaction, however, bears the very unpleasant feature of creating an exacerbation of the disease. But where there are no other methods of diagnosis and when the importance of diagnosis outweighs the risk to the individual the reaction might be put to the test. Experimentally its use is certainly pardonable in checking up cases of suspected cures where release of the patient from the leprosarium is advocated, and in preventing spread of the disease by immigration from the endemic zones.

It is a known fact that the course of leprosy is hastened by intercurrent infections even of a very mild nature. A scant experience with the disease has led me to believe that the same result may follow on reactions to vaccine subcutaneously administered and on anaphylactic reactions. Hesitation to put this theory to a test, does not permit me to state the latter with any degree of positiveness.

Medicolegal Notes.

Admissibility in Evidence and Authentication of X-Ray Plates and Prints.—In an action for personal injuries to the plaintiff's jaw, sustained in a collision, the jaw being in such a condition that the plaintiff could not open his mouth to any extent and his teeth did not track, it was urged that the testimony of two witnesses for the plaintiff, Drs. Lange and A. R. Johns, with reference to *x*-ray plates and prints showing the condition of the plaintiff's jaw, should have been excluded, because there was no certainty that the prints made by Johns were from the *x*-ray plates made by Lange, and the accuracy of the plates was not sufficiently established to make the evidence competent. Dr. Lange qualified as a specialist in *x*-ray work. He testified in substance that he made the plates, and that each was an accurate representation of what it purported to represent. While he did not know whether he made the prints or not, he stated that the prints were accurate reproductions of the plates. The plates and prints were marked and filed as exhibits with Dr. Lange's deposition, and were afterward delivered to the clerk of the trial court. At the trial Johns gave his testimony in person. He stated that he got the plates from the plaintiff and made the prints from these, and that the prints were a correct reproduction of the plates. Since the plates were identified by Dr. Lange and were marked by the notary, and Johns testified that he made the prints from those plates, there could be no doubt that the prints were made from the plates made by Dr. Lange, and, since the accuracy of both the plates and the prints was testified to by Dr. Lange, and the accuracy of the prints was testified to by Johns, it was held, not only that their evidence was admissible, but that the plates and prints were also admissible.

Practising Medicine Without License—Separate Offenses—Insufficiency of Verdict—Employment by Another Physician.—In proceedings for practising medicine without a license from the Missouri State Board of Health, the defendant appealed from a conviction. The Missouri statute provides for three separate and distinct offenses, practising medicine, attempting to practice medicine, and advertising as a physician without a license, and it was held that the defendant being charged with all three of the offenses, the verdict should have been specific as to whether he was guilty of one or other or of all of them. As the matter was submitted to the jury, some of the jury may have believed him guilty of one of the offenses and some of the other. The defendant was entitled to have twelve men believe him guilty of either one or all of the stated violations of the statute. The defendant was given the minimum punishment, a fine of $50, and it was plain that the jury only intended to convict him of one offense, but which one the jury did not say. The information in the case should also have been in three counts, one for each separate offense. The defendant admitted that he was a chiropractor. Under the law of Missouri one engaged in chiropractic is practising medicine. The defendant contended that he was engaged as an assistant to a regularly licensed physician, and offered evidence to this effect, which the trial court excluded. This was held not error, as the defendant could not escape the effect of the statute by showing that in practising his profession he was employed by another and acted under another's direction. The judgment of conviction was reversed and the cause remanded.—State v. Young (Mo.), 215 S. W. 499.

Practising Medicine Without Certificate.—In a prosecution for practising medicine without a certificate from the Virginia State Board of Medical Examiners it appeared that the accused for a number of years had been engaged in the business of selling, through a drug store, certain proprietary medicines of his own manufacture. He maintained an office in the city, where his patrons would resort to consult him, and he would advise them which of his remedies, if any, was suited to their case, and direct them to the drug store where it could be bought. Subsequently he had his business incorporated and sold his medicines direct to the trade without the intervention of a druggist. He described his general course of business substantially as follows: When a customer would call for a particular medicine, he would sell the remedy wanted, while others would describe their symptoms, and he would prescribe which of his medicines would suit the case. In such instance he stated that he made no charge for advice and only received the price of the medicine. The trial court granted an instruction to the jury requested by the prosecution that if the defendant announced in any way to the public that he was ready to examine human beings physically, to diagnose their ailments, and furnish for compensation a remedy which would relieve the same, or did engage in the business of examining human beings physically, diagnosing their ailments, and furnishing medicine which he claimed would relieve them and receive pay for the same, then he was guilty as charged. It was held that the instruction was practically in the language of the statute and that the jury's verdict of guilty was fully sustained by the evidence.—Pickard v. Commonwealth, Virginia Supreme Court of Appeals, 100 S. E. 821.

Statute of Limitations Governing Time of Actions.—The Ohio Supreme Court holds that in an action for a breach of the contract between a surgeon and patient, the statute of limitations does not begin to run until the contract relation is terminated.—Bowers v. Santee, Ohio Supreme Court, 124 N. E. 238.

A CASE OF BERIBERI (?) IN SPAIN.

MARTINEZ, Director of the Institute for Tropical Medicine at Grenada reports this case at length in the *Archives médicales Belges* for April, 1920, lxxiii, 4, just received. The same author had previously reported the first cases in Spain of amebic dysentery, infantile kala azar, and cutaneous leishmaniosis (Oriental boil.) Beriberi was found on the littoral of the Province of Grenada. The sole patient was a man of 52, a fisherman, who also worked as a day laborer and shepherd. He was married and the father of two healthy children. He worked during the same year in semitropical and cold mountain temperatures, going without transition from seashore to mountain. There was no evidence of any social disease, either alcoholism or syphilis. As to diet he ate but little meat; pork occasionally on festivals or goat meat, the latter mostly of goats which had slipped and fallen from mountain heights. He ate freely, when on the shore, of fried fish, potatoes, rice, peppers, and tomatoes. There was plenty of oil used in cooking and serving. He ate also of chick peas, maize and rye. In general his diet seems to have been adequate while fishing. From fishing in July he passed without transition to sheep herding in the mountains at an altitude of 7,000 or 8,000 feet. There was naturally a sharp transition in his diet. Most of the year he led a life of solitude—the ordinary life of a shepherd; and it is here during this period that we have to look for dietetic shortcomings. Once a week he laid in both bread and oil and was clad throughout in sheepskins like a cave man. Naturally he was much exposed to cold.

Early in January, 1916, he exhibited prostration, malaise, colic, saburral tongue, and constipation. He improved not at all under purgative regimen and in addition began to have headache and other painful symptoms. Salicylic acid and warm baths were of no avail, and to increasing pains, often shooting in type, were added symptoms of motor paresis and abolished reflexes. The diagnosis of polyneuritis was readily made. The patient was removed to the local hospital, when, on account of extreme debility and semicachexia, he had to keep to his bed. The muscular masses of the body were seen to have shrunken notably and there was edema of the ankles. The author continues the results of the neurological examination in great detail and shows that various spinal diseases could be excluded and that the paraplegia must have been due to neuritis. Further, with the diagnosis of polyneuritis not in doubt, all of the etiological types of this affection could be excluded, save only beriberi. Edema is one of the symptoms of this affection. But the best argument perhaps in favor of his diagnosis was the response to nourishing diet rich in vitamines. Recovery was tedious and the patient had the full benefit of arsenic, phosphorus (phosphates), strychnine, massage, etc.

While the author is very certain of his diagnosis it is incomprehensible that a Spanish physician should not even mention lathyrism under differential diagnosis. According to Bass differentiation in border line cases is all but impossible. The usual test is absence of edema in lathyrism, but the edema in this case seems to have been very slight. This subject had flaccid paraplegia while in lathyrism paraplegia is more of the spastic type. In regard to the consumption of vetches, etc., it is not certain that chick peas are among those accused of causing lathyrism, and the patient seems to have eaten them only in the form of soup. Unless other cases like the one reported come to light the diagnosis of beriberi will probably be disputed.

IS LETHARGIC ENCEPHALITIS A FORM OF RABIES?

DELAUNAY, director of the School of Medicine and Pharmacy of Poitiers, advancing this hypothesis in the *Gazette hebdomadaire des Sciénces Médicales de Bordeaux* for Aug. 8, 1920, xli, 32, does not, of course, mean that lethargic encephalitis is communicated necessarily by inoculation, but believes that it may be due to the exciting cause of rabies. Careful comparison of the two diseases shows a surprising concordance. Both are polymorphous and the polymorphism depends largely on the region attacked. But it is well to admit at the outset that the Negri bodies have not yet been found in encephalitis, while certain histological changes characteristic of encephalitis have barely been seen in rabies, lymphocytic infiltration of the vascular sheaths, micro-hemorrhages, etc.

The evidence to connect the two maladies must necessarily be very strong to offset these discrepancies. Both are due to some unknown agency which passes through the tightest filter and which is neurotropic in a high degree; in both affections the cause can persist in the nervous system a long time in a state of latency. In animal experiment the rabbit inoculated with the virus of encephalitis behaves in all respects as when inoculated by rabies. Strangest of all, in both affections the microorganism leaves the body by the saliva, this fact having only recently been shown for encephalitis by the Americans Strauss, Hirschfeld, and Loewe. The good results from pilocarpine are explained in this fashion.

The war caused a let-up in the supervision of mad dogs, and rabies in man showed a sudden increase, even reappearing in England after years of absence, while in France it was prevalent on a scale long unheard of. It is conceded that the great majority of encephalitis victims have not been bitten by dogs, cats, or other animals, but the author as far back as 1902 advocated the view that rabies is transmissible without the causation of a wound, the germ being present in the saliva. More cases of encephalitis occur in rural than in urban districts, and in the former the risk of contamination from dogs is greater. Roux and Nocard proved that the saliva of dogs may be infected several days before rabies appears—four days and even much longer in the exceptional case. In regard to alimentary communication Decroix was heroic enough to ingest the saliva of a mad dog and escaped infection, but alimentary transmission has been established, so Delaunay asserts, by the experience of Gohier, Fernel, Schenkins, Sanzoni, and Alfadi. The milk of hydrophobic cows and other rabid animals has been shown to be infectious to animals, and even the milk of women victims of rabies has been found infectious by four of the authors above enumerated. It is therefore not impossible that infected butchers' meat, milk, etc., have been responsible for transmitting the virus to mankind and that rabies thus contracted might run a milder course. It is of course conceded that many recover from encephalitis, and that rabies is 100 per cent. fatal is the general belief. But the latter conclusion is not correct, for the death rate is not 100 per cent., but 99 and some fraction, since recovery from rabies has been attested by Chantemesse, Laveran, J. Roux, Lebell and Veresco, and Courmont and Lesieur. In the case of Lebell and Veresco the recovered case was in an infant bitten in the face. The author might have added that the malady of Dubini, believed to have been encephalitis lethargica, had an extremely high mortality. He concludes with the hope that the subject will be threshed out in the Pasteur Institute. It is possible that influenza may have sensitized patients to this form of rabies.

THE CAUSE OF DENTAL CARIES.

A GREAT deal has been written in recent years concerning dental disease and very many exaggerated statements have been made. It is undoubtedly an extremely serious problem in all civilized countries, for it is only when primitive people receive the perhaps doubtful blessings of civilization that dental caries is introduced. Whether pyorrhea alveolaris is such a grave condition as to warrant the extraction of every suspected tooth is a matter at least open to argument. Medical opinion is now generally against the wholesale extraction of teeth. However, one point does not admit of argument and that is that the prevention of dental caries or any other form of tooth or gum affection, is better by far than the most efficient or radical treatment. What then is the underlying cause of the condition? It seems that there are those who affirm that the fundamental causes are unknown and that therefore it is useless to lay down definite rules for prevention. According to an annotation in the *Lancet* of Aug. 21, Dr. R. A. Lyster, at the recent meeting of the British Dental Association, is reported to have made remarks of this tenor. As is pointed out, if this statement is allowed to gain currency it will tend to undermine belief in the excellent work that has been done on the etiology of dental disease and on which the present rules for prevention of the condition are based. It is held by many that dental caries is due largely to our excessive carbohydrate diet and the enormous consumption of sugars, especially those of the monosaccharide group. Certainly in the case of periodontal disease it is obvious that the lodgment of food in the interdental spaces is a prominent, if not the most prominent factor in the causation. Dr. Harry Campbell of London is one of the chief and most persistent exponents of the harmfulness of jamming easily fermentable saccharine material into the crevices between the teeth and he holds that this is one of the readiest means at our command to promote their decay. Surely then if certain articles of diet and those of the monosaccharide group in particular are believed to be potent factors in the causation of teeth decay and of other forms of dental disease, steps might be taken, particularly of an educational character to prevent the most prevalent and in many ways, the most unpleasant disease of the human race.

In a letter contributed to the Sept. 11 issue of the *Lancet* the statement was attributed to Prof. J. G. Adami that the teeth of the American citizen were far better than those of the inhabitants of the British Isles. The writer of the letter, however, doubts the validity of the statement and prophesies that now American has gone "dry," and in consequence more candy is being consumed, the dental surgeons and doctors will be still more busy. The truth is that Americans of all classes have always been careful of their teeth, not by dietetic preventive measures at all, as we are the largest eaters of candy in the world, but it is a national characteristic to go to the dentist as soon as any signs of dental decay present themselves. From childhood on, dental care of the teeth is meticulously followed and it is considered somewhat of a stigma not to have even and white teeth, and where nature fails art steps in. On the other hand, the mass of the British people have been notoriously neglectful of their own teeth and of the teeth of their children and it is only within recent years, since the war in fact, that attention has been drawn to the bad condition of the teeth.

SOME VITAL STATISTICS.

THE quarterly return of marriages, births and deaths in England and Wales, issued on Aug. 14 of this year by the Registrar-General, contains much that is interesting. The figures given are of course subject to those variations that are seasonal as well as annual, to what may be called accident as well as to definite causation. They must

be controlled over a period of years, corrected for differences in the mode of collection, and subjected to expert examination, before it is safe to make them the basis of general inferences. Superficially looked at, they would appear to be satisfactory. The population seems to be in process of recovery from the war, and the excess of births over deaths is approximately three times the average for the corresponding quarter in the years 1917, 1918 and 1919. There was no great epidemic, although influenza was stated to be the primary or contributory cause of death in over four thousand cases.

Illegitimate births increased twenty-two hundred, but not in proportion to the total increase, being in round figures one in every twenty births this year as compared with one in every fifteen in 1919. The increase was quite evenly distributed over the counties, the exceptions, in which there was an actual decrease in illegitimate births, being in some of the less populous and preponderatingly agricultural counties, such as Oxford, Wilts, Devon, Dorset and Hereford. Male births exceeded female in the proportion of 1,048 to 1,000, a slight increase over the proportions for the last few years, but well within the range of what may be called normal variation, and insufficient to support the popular belief in the effect of war on the determination of sex.

An interesting comparative table of the birth and death rates of certain European cities for the second quarter of the year seems to show that economic conditions are not hitting Germany to any marked degree. The death rate for London was 12.5 per 1000 of the population—calculated as for the entire year; for Antwerp 9.3, Amsterdam 9.7, Stockholm 12.5, Christiania 11.6, Berlin 13.2, Hamburg 12.6, Leipzig and Dresden 12.3, Cologne 14 and Frankfort 10.4. The London birth rate, similarly reduced to an annual rate was 28.3, that for Antwerp 21.9, Amsterdam 23.9, Stockholm 18.6, Christiania 22.7, Berlin 17.8, Hamburg 22.1, Leipzig 23.1, Dresden 22.2, Cologne 26.9 and Frankfort 20.4. On the other hand, the figures reported from Vienna and Prague show lower birth rates and higher death rates.

VACCINES IN THE TREATMENT OF CHILBLAINS.

VACCINE treatment may be said to be in the stage of evolution. It is developing slowly and knowledge concerning it is accumulating somewhat slowly, but on the whole progress is being made. There are certain complaints which appear to lend themselves obviously to this form of treatment, some skin diseases for example, and in many cases confidence in vaccine treatment has been amply justified by the results. Chilblain, which hardly falls under the head of skin affection, is a minor ailment which has been treated successfully by vaccine. Robert Robertson writing in the *Prescriber* for August, 1920, states that for the last five years he has treated a large number of cases with a great measure of success. This treatment was devised on the following grounds: It seemed to Roberston that the chilblain was the first stage in Raynaud's disease, being dependent on a paresis of the venules, so that, while the blood got into the extremities the venules were incapable of allowing it to drain off. He points out that a further and a very common stage of the disease is a paresis of the arterioles which prevents the blood from even entering the fingers or toes, producing either Raynaud's disease or that common condition where the fingers become waxy and devoid of blood. His view is that the paresis of the venules is caused either by some toxin generated in the intestinal canal, or by the direct transference of bacteria from the intestinal canal into the blood, thus acting on the peripheral blood vessels. The paresis devitalizes the tissues of the extremities and renders them subject to attack by surface organisms.

Basing his action on this theory of the pathogenesis, Robertson used a combined vaccine of *Bacillus coli*, a pneumococcus obtained from the bowel, and *Staphylococcus pyogenes*, the first two organisms being directed to the bowel condition, and the staphylococcus used for the most prevalent cause of local suppurative conditions; also he found it is sometimes an advantage to add the ordinary *Streptococcus pyogenes* to this combination. The dose of the *Bacillus coli* must be kept low, otherwise a serious reaction with feeling of depression is caused. It is stated that, as a rule, three or four inoculations are quite sufficient to overcome very severe chilblains. The effect seems to last for three or four months, but has usually to be repeated once again during the winter. Patients applying for protective inoculation have two inoculations given them early in October, the interval between being ten days. If the patient keeps free it should be repeated in February. Robertson thinks that *Bacillus coli* is the key germ and that with its disappearance from the body one gets a cessation of the serious effects set up by other organisms which can work only in conjunction with it.

CONSERVATIVE TREATMENT OF BONE SARCOMA.

LARGELY under the influence of the Lyons School of surgeons, recent years have seen systematic efforts at a conservative surgery of sarcoma of the long bones. In an article which appeared originally in the *Revue d'Orthopédie* and is found in abstract in *La Presse Médicale* for June 30, xxviii, 44, Estor and Aimes report upon 147 so-called economical operations for this condition. It is to be noted that a prognosis based on the histological finds alone often is reversed by the outcome of the case; that encapsulation is a factor to be reckoned with in prognosis, especially early in the case; that lymphnodes are rarely implicated; that the subject himself often refuses mutilating interventions; that economic operations when successful give excellent functional results; and finally that radical operations may fail in cases with inherently bad prognosis, often because of overlooked latent metastases. Three sorts of conservative operations have been tried out—ablation of the tumor alone, ablation

plus excochleation of the focus, and resection. As the first two can seldom be justified the question is narrowed to the alternative of resection or amputation. The late Kocher claimed that a conservative operation should always be tried first and several successive ones are sometimes practicable. In the upper extremity it is always wise to endeavor to conserve the hand, and a comparison of resections and amputations has shown that the former are as good if not better than the latter in the final outcome. In the lower extremity salvage of the foot is not so essential, but the amputation should be as low in the continuity of the bones as is compatible with firm support. Amputation or disarticulation is indicated in round-cell tumors, rapidly growing tumors, ulcerated or infected tumors, and those which have notably involved the soft parts. At the other extreme are encapsulated giant-cell and spindle-cell sarcomas and those of slow evolution, beginning growths, etc.

Rare Earths in Medicine.

THE original member of this group was cerium oxide, according to an article by Professor Denigès of Bordeaux in the *Gazette hêbdomadaire des sciences médicales de Bordeaux* of June 27, 1920, xli, 26. Although he does not allude to it, cerium oxalate came into medical use as a succedaneum for the insoluble bismuth salts. Yttrium and lanthanum developed no medical status. The original use of didymium in the construction of Welsbach mantles is of indirect medical significance. The number of alleged metals of the cerium group now amounts by actual count to thirteen, some of which are doubtless mixtures. Some of the less known are dysprosum, neoholmium, terbium, eropium, neoerbium, and lutecium. The cerium group in the narrower sense comprises cerium, lanthanum, praseodymium, neodymium, and samarium. Cerium is now known as a remarkable oxidizing catalyser which can increase the power of radiation of incandescent thorium in the proportion of 1 to 100. Rare earths come from but few ores—cerite, gadolinite, samarskite, etc. The thorium industry has wrought a great change in the status of these earths. Thorium, while not of the cerium group, is obtained almost entirely from monazite, an ore which with a phosphatic base contains numerous rare earths. Thorium has now supplanted the cerium minerals in the construction of incandescent mantles. As a result there are many oxides of rare earths available for study as by-products.

Sequelæ of Appendectomy.

THIS subject is discussed by Enriquez in the *Journal de médecine et de chirurgie pratiques* for June 10, 1920, xci, 11. The author refers to the operation when performed for chronic appendicitis. It is here that the indications for intervention are debatable, for many subjects are actually worse after operation. The percentage of 25 is rather low in the author's opinion, although he is a surgeon writing from the surgical viewpoint. The operation is far from simple, whether the chronic condition follows acute attacks or occurs *de novo*. Various complicating or secondary conditions are not necessarily affected by the intervention and persist after the latter. If in these complicated cases we simply isolate and tie off the appendix, there remains a "syndrome of the right iliac fossa" due to the presence of one or a number of conditions, as pericolitis, epiploitis, Lane's kink, cecum mobile, etc. The syndrome may be sufficiently like that present before intervention, with special reference to gastroenteric manifestations. Two new symptoms often appear—increased degree of constipation and abdominal crises. The latter are apt to appear during attempts at defecation. Anemia and evening fever may be present, and in general there is often the suggestion of tuberculous peritonitis. The author goes extensively into the symptomatology of two main types of appendectomized patients as outlined by clinical and *x*-ray finds. In one the condition is termed predominantly inflammatory, while in the other it is predominantly mechanical. In order to throw light on the preexistent and postoperative components the patients should be carefully *x*-rayed under proper control before operation to determine the amount of mechanical interference. In regard to intervention the author would abandon simple appendectomy through a small incision in favor of a more radical procedure.

Saint Anthony's Fire.

THIS mysterious medieval malady, which is best visualized as a very painful and mutilating gangrene of the extremities which occurred in mass incidence and has been variously identified as erysipelas, malignant carbuncle, ergotism, etc., is considered at length by Durodié in the *Gazette hêbdomadaire des sciences médicales de Bordeaux* for June 13, 1920, xli, 24. The word "fire" which occurs in several of the common names of the affection naturally suggests erysipelas, but otherwise the resemblance is not striking. The deaths sometimes reached high figures, as 40,000 for the South of France in 1020 A. D. Clearly we know of no malady of this description which could cause such mortality in our own day. The word "acro-ignis," used by one author, suggests pellagra, but the two affections have never been confounded. Durodié writes at great length with many unfamiliar citations of much interest. In a dictionary of the ancient French language he finds *ignis sacer* defined simply as gangrenous erysipelas. One ancient chronicle makes *ignis sacer* the medieval plague. The hemorrhagic intestinal disorder which destroyed Henry V of England was termed by two chroniclers St. Anthony's fire, although evidently of internal in place of external location. Facts like these may suggest that death was due to the intestinal form of malignant pustule. The identity of the latter affection with St. Anthony's fire has recently been claimed by a German historian whose name escapes us—the paper to this effect was read shortly before the war at a session of a new society devoted to the history of medicine and the opinion was noted at the time in the MEDICAL RECORD. But Durodié comes out firmly for ergotism as the actual disease. It is beyond doubt that the latest recorded epidemics were of this nature, but the type of gangrene has apparently undergone some change during the centuries.

Anthrax Cured with Horse Serum.

According to de Rezende in the *Brazil-Medico* for May 29, xxxiv, 22, carbuncle is very rare in Brazil. On April 16 in one of the clinics at Guaratingueta a white man presented himself with a lesion on the back of his right hand. The member was much swollen and inflamed and there was a marked systemic reaction of headache and fever. The pain was atrocious and an erysipelatous redness extended up the arm and on the trunk. The history pointed to a possible inoculation, the surface of the hand presenting numerous abrasions which might serve as ports of entry. The infection appeared to start from the first phalanx of the thumb, the first lesion showing a little pus, and quickly extended over the entire dorsum manus. The parts were in a state of hard edema, and incisions seem to have been made only to relieve tension and pain. On the opposite hand there was a single pustule over the head of the fifth metacarpal bone. The description of the lesion does not at all agree with that of ordinary or simple carbuncle, and the history of exposure to a victim who had "died of carbuncle" makes it certain that the author refers to "malignant pustule," although nothing is said which points with absolute certainty to that affection We know, of course, the two kinds of "carbuncle" are continually confounded in literature, and the writer was once present at a discussion in which some of the members were speaking of anthrax and others of simple carbuncle, without seeming to be at all aware of the confusion in terms. Since Langone of Montevideo had obtained good results in "carbuncle" from horse serum, the author began its use and continued to inject it under the skin of the abdomen over a period of two weeks or until the subject was out of all danger. The entire back of the hand and wrist sloughed with an enormous loss of substance.

News of the Week.

"Livable Fees" Demanded by Vienna Physicians—News comes from Vienna, via Berlin, that the doctors of the Austrian city have struck for "livable fees." The physicians connected with the Kranken-Kaase or State Sick Relief Fund, demand 48 to 110 kronen a day. Under the present system they receive 24 to 55 kronen (approximately 35 to 75 cents) per day.

Twenty Millions Needed for Starving Children in Europe.—Checks aggregating $605,194 were despatched last week by the American Relief Administration to the food administrators of central and eastern European governments, this amount representing the difference between operating costs and money received under the Hoover food-draft plan. The sum will be used for food for destitute children, of whom there are said to be 2,500,000. Of this number the amount forwarded will provide one meal a day for one month. To provide in the same way for the entire number of children, it is estimated, would require $20,000,000.

American Hospital Presented to Italy.—The Committee on the American Tribute to Italy, through Mrs. John Adams Drake, has offered a children's hospital to Italy. It has been decided to call the institution "International Child Welfare At Rome."

Near East Hospital Destroyed by Fire.—A cablegram from Constantinople announces the destruction by fire of the Near East Relief Hospital at Talas, Anatolia. There was no loss of life, and a third of the provisions and instruments were saved.

Government Makes No More Anthrax Serum.—Answering complaints regarding the discontinuance by the Government to produce anthrax serum, Dr. John Mehler, Chief of the Federal Bureau of Animal Industry, is quoted as saying the bureau discontinued the preparation of the serum because Congress cut off its appropriation for that work on July 1 last and because the horse which had been used by the bureau for the production of the serum died six or eight weeks ago and there was no other horse for the purpose.

Smallpox on Liner "Mobile."—A Czecho-Slovak steerage passenger on the White Star liner *Mobile* from Liverpool developed smallpox on the voyage across the Atlantic, whereupon all passengers, both cabin and steerage, and all members of the crew, with one exception, were vaccinated before the ship was allowed to land. A steward, who said he had been in a bubonic plague epidemic, had seen the devastation of Asiatic cholera, beriberi, and yellow fever, and had never been inoculated, drew the line on undergoing this formality for smallpox. He was placed in isolation until the ship sails again. The smallpox patient was sent to Swinburne Island.

Coffee Drinking Increases.—According to figures compiled by the Bureau of Foreign and Domestic Commerce of the Department of Commerce more coffee was consumed in the United States during the year ended June 30 than in any previous year on record. The total coffee consumption in continental United States for that period was 1,358,000,000 pounds and the per capita consumption 12.7 pounds. This is a total increase of 399,000,000, and a per capita increase of 3.71 pounds over the preceding twelve months. It is estimated, on a basis of forty cups to the pound, that this increase is equivalent to sixteen billions of cups of coffee.

Birth Rate Increase in United States.—The birth rate for 1919 in this country is estimated at 2,500,000, based on statistics representing a population of 31,000,000. The figures covered 269 cities, in which 680,000 babies were born during the year.

Drunkenness Increasing.—Chief Magistrate McAdoo finds the law of adaptation effective in New York City in one respect, at least,—"the people are adapting themselves to the situation and finding means of getting intoxicants." Figures for the first six months of this year show that as national prohibition continues drunkenness, temporarily checked, is increasing to figures that prevailed before prohibition laws went into effect.

Warning Against "Fake" Orange Beverages.—The Bureau of Chemistry, United States Department of Agriculture, under the Pure Food and Drug Act, has instituted prosecutions against the misbranding of orange beverages. Cases are now in the Federal courts and, pending decision, the food officials charge that some firms are still using deceptive labels. It is alleged that mothers, in some

instances, misled by the labels and other advertisements, are giving "fake" orange beverages to their children under the impression that they are following the orders of the physician. The Bureau of Chemistry has found that in most instances these beverages contain no orange juice, but are sweetened carbonated water, flavored with a little oil from the peel of the orange and artificially colored, and that they are lacking, therefore, in the organic acids and the vitamines which give medicinal value to the genuine orange juice.

Federal Agents Seize Drugs.—Agents of the narcotic squad of the Internal Revenue Department recently seized cocaine and morphine which they valued at $250,000, most of it being taken as it was about to be delivered to a downtown chemical concern.

Increase in Chemical Exports.—According to statistics published by the American Chemical Society, the total value of exports of all chemical and allied products for 1920 is roughly estimated at a billion and a quarter dollars,—a slight increase over 1918, and about four times the figure for 1914. Exports of medicinal and pharmaceutical preparations alone were valued at $20,000,000 in 1920, or twice the total for 1918, and about three times the total for 1914.

Typhoid Carriers in Massachusetts.—The Massachusetts State Department of Health possesses a list of fifty-one known carriers of the typhoid bacillus who are thought to be responsible for 493 cases of typhoid fever. Twenty-one of these individuals transmitted the infection through milk, and eighteen through their occupation as food handlers. The remaining twelve could have transmitted the infection either through food or by direct contact.

New York Community Trust.—This organization, which is composed of men prominent in the business and professional affairs of the city, has for its object the encouragement and promotion of gifts for charitable, benevolent, and educational purposes. The disbursements are controlled by a Distribution Committee. Frank J. Parsons, Vice-President of the United States Mortgage and Trust Company, is Acting Director of the trust.

Dr. Louis Fischer has removed his office to 33 West Seventy-third Street, New York City.

The International Congress on the Classification of the Causes of Death, which will meet in Paris at an early date, will be attended by Dr. Haven Emerson former Health Commissioner of New York City, representing the Public Health Association; Dr. F. J. Monaghan, Assistant Health Commissioner, and Dr. W. H. Guilfoy, Director of the Bureau of Vital Statistics of the Health Department, representing New York City; Dr. Otto Eichel of the Bureau of Vital Statistics of the State Department of Health; Dr. W. H. Davis, of the United States Bureau of Census, and George H. Van Buren, Statistician of the Metropolitan Life Insurance Company.

The American Child Hygiene Association will hold its eleventh annual meeting at St. Louis during the week of October 11-18.

Charitable Bequests.—By the will of the late Max J. Breitenbach, the following bequests are made: $25,000 to the New York College of Pharmacy, connected with New York University; $5,000 to each of the following: Sanitarium for Hebrew Children of the City of New York, Montefiore Home, Hebrew Infant Asylum, Home for Aged and Infirm Hebrews, Hebrew Benevolent and Orphan Asylum, Beth Israel Hospital, Hebrew Sheltering Guardian Society, Widowed Mothers' Fund, Lebanon Hospital, Jewish Maternity Hospital, United Hebrew Charities, and the Crippled Children's East Side Free School; $3,000 to Mt. Sinai Hospital; $2,000 each to the Jewish Protectory and Aid Society, the Educational Alliance, Young Men's Hebrew Association, and the Young Women's Hebrew Association. A gift of $1,000 is made to the Hospital at Albany, Ga.

Memorials to Carlos Finlay.—As a culmination of long sustained efforts, memorials to Finlay as discovery of the agent of transmission of yellow fever will be erected in both Cuba and Spain. The monument of marble or bronze to be erected in Cuba is in charge of Mateu, who also had charge of similar memorials to General Maceo and the martyr poet Zenea.

Obituary Notes.—DR. JOHN D. COLE of New York City died at Alexandria Bay, N. Y., September 25, in his sixty-fourth year. He was graduated from Hahnemann Medical College and Hospital, Chicago, in 1882. He was a member of the Homeopathic Medical Society of New York.

DR. CHARLES F. ROBERTS of New York City died September 27 at the age of seventy-eight. He was graduated from Bellevue Hospital Medical College in 1867. He served as an apothecary during the Civil War, and was Sanitary Superintendent of the Health Department, New York City, from 1893 to 1907.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, September 10, 1920.

War Asylums.—A good deal of criticism has been leveled at the treatment accorded in the asylum war hospitals to soldiers rendered temporarily insane by shell shock. This adverse comment has been analyzed and officially answered in a report on the work of these hospitals by Sir Marriott Cooke and Dr. C. Hubert Bond, Commissioners of the Board of Control, which has just been issued as a White Paper. This report completely exonerates those responsible for the management of these institutions and their medical and nursing staffs. The board is confident that the supervision in all these war hospitals and institutions has been so strict, and that the patients have had such opportunities of daily access to the medical officers and others of the higher officials that systematic ill-treatment has been and is impossible without its speedily becoming known and being severely dealt with.

The scheme when fully developed, supplied twenty-four hospitals, which, it is stated, without exception, were acknowledged by all the many expert authorities who inspected them to have afforded facilities for surgical and medical treatment in all respects equivalent to those available

at the best military and civil hospitals in the country. These twenty-four hospitals provided, with some hutments, as many as 27,778 permanent beds, and with extensions could accommodate 31,000 patients. The number of patients treated in them up to May 15 this year had been 482,949, approximately equivalent to more than one-sixth of the total number of sick and wounded men from all fronts during the war. The scheme started with nine asylums, which had to be cleared of their insane patients. This rapid transference of some 12,000 patients, including many dangerous and violent cases and many who were aged and feeble, was effected without any untoward event.

Of the total number of all classes of patients that were treated the number that died, 3,258, was equivalent to only 0.67 per cent. In addition to the physically sick and wounded men, the large total of 38,440 patients suffering from mental breakdown or nervous diseases had up to May 1, 1920, contrary to the original intention of the scheme, been treated either in a section of one or other of the war hospitals, or in the seven smaller hospitals devoted exclusively to the treatment of soldiers suffering from mental or nervous complaints. The hospitals have been referred to in gratifying terms by the Army Council, and many eulogistic comments have been made by patients, their friends, and others who had visited the hospitals.

Scarcity of Nurses.—A great lack of nurses is being experienced in all parts of Great Britain, and, of course, is a serious question. While large city hospitals are suffering from this dearth of nurses, the smaller institutions are said to be feeling the situation even more acutely. Nursing as a vocation seems to have become unpopular as girls are chary of coming forward for training. Neither does there appear to be any likelihood of a change for the better. Many reasons are given for the existing state of affairs and naturally these vary considerably. However, there is agreement on some points. All are agreed that the age at which a would be nurse is allowed to begin training is too high. A woman must be 23 ere some of the largest hospitals will accept her. She can go to other institutions before she reaches this age, but the time she spends in them does not count when she commences training in one of the big hospitals. The result is that if a woman makes up her mind to embark on the career of a nurse, she must either go to an unrecognized institution at the age when she is adaptable and likely to learn and possesses the most enthusiasm or she must wait until she is 23. Her friends will probably be earning money and comparatively independent during this time of waiting. The outcome is that when they have attained to the age required they are already engaged in a remunerative employment and are not disposed to change it for the hard work, small degree of comfort, and miserable pay of a probationer. The hospitals in this respect seem to have made a mistake. Girls considerably under the age of 23 performed excellent nursing service during the war and why they should do less effective work in time of peace is hard to say.

Naval Medical Officers' Rank.—The British Admiralty have decided that in future medical officers who entered the service on or after August 4, 1914, will not have to pass a qualifying examination for the rank of surgeon lieutenant-commander. These officers, however, when they have obtained, between two and six years' seniority in that rank and after a preliminary course of study will have to qualify by examination for promotion to a higher grade. Surgeon lieutenant-commanders will be eligible for accelerated promotion according to the class of certificate obtained in the qualifying examination. For a special certificate the advantage may be 18 months, and for a first class certificate 12 months. In order, however, to obtain accelerated promotion, the officer must also have been recommended for advancement. Two attempts to pass the examination will be allowed, but surgeon lieutenant-commanders who fail to pass at a second trial will be compulsorily retired with a gratuity which shall not exceed £100 for each complete year's full pay service nor be above a maximum of £1,000. Officers who entered the service before August 4, 1914, may voluntarily take the course and sit for the examination, and should they receive the requisite number of marks the advantages described above will also be open to them.

Street Accidents in London.—In a previous letter I mentioned the fact that since the war street accidents had increased largely in London and the report thereon published recently by the Commissioner of Police affords full confirmation of this statement. Within the London Metropolitan Police area during 1919, 688 persons were killed by traffic. During the same period 19,685 people received injuries in the streets, most of which would not have come to the knowledge of the police had they not been serious. The toll is heavy and promises to be more heavy in the years to come. In 1919 the accidents were more than in 1918 and in 1913 the year before the war the deaths in the streets by accidents numbered less than 600. The underlying cause for the increase is obviously the fact that mechanical transport is almost wholly employed nowadays and just as obviously London built on haphazard principles and with many narrow and tortuous streets is not able to cope with the flood of swift and heavy traffic which has been poured into it. The question is, what can be done to alleviate the situation short of reconstruction, which, if possible, would take time. The control of traffic by the police is practically perfect. It has been suggested that there is a good deal of careless driving or perhaps reckless or incompetent driving and it has been further suggested that every applicant for a driving license should be required to pass a test of efficiency. In London this would be a stupendous task and the only remedy appears to be the carrying out of the maximum safety first. It would be interesting to compare the statistics of street accidents in Greater New York and London, which more nearly approach each other in population among the big cities of the world. New York is more modern and its streets are wider and straighter, but, on the whole, perhaps the conditions do not differ very widely.

Municipal Hospitals.—The proposal of the

Ministry of Health in a bill recently introduced by the Minister, Dr. Addison, to give local authorities the power to maintain hospitals or to subscribe to voluntary hospitals in their area, is meeting with strong opposition. It is argued that the proposal practically amounts to throwing the voluntary hospitals on the rates and compelling or asking the already overburdened rate payers who consist most largely of the lower middle class, to maintain hospitals used mainly by the now comparatively rich working class. Moreover, hospitals are obviously mostly needed in populous areas, in manufacturing areas, and near congested thoroughfares and dwelling places. And these are the very areas of which the inhabitants can least afford further additions to rates which already press them cruelly. It is pointed out that the clear result will be that wealthy districts will be able to supply and maintain hospitals which they do not require, while districts which are in urgent need of additional aid for their hospitals will not be in a position to provide that aid. Again, it does not seem reasonable to suppose for one moment that the rate payers of any large cities containing hospitals specially equipped for treatment of various diseases and therefore full of patients from all parts of the country, will tax themselves for the benefit of the inhabitants of other counties. It is allowed on all hands that the voluntary system for hospitals is not now equal to the strain which is being placed upon it, and it is recognized that steps must be taken promptly to relieve the situation. The profession as one man is against state hospitals, and it seems that the ratepayers are against municipal hospitals, so what is to be done? It is curious that, little has been said in discussing the hospital crisis concerning the introduction of the pay or partial pay system, although a beginning has been made in this direction. If such a system were introduced it appears that many of the obstacles now in the way would be removed. The working classes who can well afford, as a rule, to pay for hospital treatment would subscribe their fair share toward the maintenance of these institutions and the middle classes would have the opportunity which has been denied them hitherto of receiving good medical and surgical treatment at a fair cost, treatment which the working classes have had for nothing or comparatively little. The arrangement would be equitable and should be workable.

The Irish Medical System.—It is pointed out in the educational number of the *Medical Press and Circular*, September 8, that the system of medical treatment in Ireland differs from that in England in certain important particulars. In London each clinical hospital has its medical school attached, which educates the students of that hospital and very seldom the students of any other. In Dublin, on the contrary, the hospitals and schools are entirely separate, and a student of any school is free to enter for the whole or any part of the course at any school or hospital he pleases.

Report for 1919 of the Medical Officer of Health for Norwich.—Public health reports provide interesting reading and therefore the report of the medical officer of health for Norwich should afford those concerned with public health matters in America grounds for comparison with cities in their country. Norwich has a population of about 130,000, and an area in statute acres of 7,923. The birth-rate for 1919 was 16.35 per 1,000, which was below that of the other ninety-six great towns of England. The gross recorded death rate was the same as the average of the ninety-six great towns, 13.8 per 1,000. The infantile mortality rate among legitimate children was 75.4, and for the illegitimate 166.7 per 1,000 births, indeed a marked contrast, and one which it is to be hoped that the Bastardy Bill introduced recently into the British House of Commons will do much to alter. Tuberculosis has decreased and Dr. Pattin, the medical officer of health, thinks this improvement is mainly due to the consumption of better food. He says that he has long placed first in importance in the treatment of tuberculous diseases not houses, helpful as good houses are, but nutrition. The boot-making industry, which is the chief industry from the standpoint of the numbers employed therein, contributes a noticeable number of phthisical cases especially among the "clickers" and he attributes this largely to the bad mechanical attitude imposed upon these workers, stooping with arms forward and chest cramped and retracted, and also to the apparent tendency of the less robust to drift into this branch of business. Eleven thousand six hundred and seventy-four children were inspected in the schools. At the dental clinic 4,339 children were attended to, 1,197 damaged permanent teeth were repaired with fillings, and 4,165 teeth were extracted.

OUR LETTER FROM BELGIUM.

LIÉGE, September 10, 1920.

Cattle Plague.—The cattle plague made its appearance in Belgium last July. It was brought in by some infected animals landed at the port of Antwerp—some zebus coming from America. The disease was first discovered in certain centers in the north of Belgium in the provinces of Flanders and of Antwerp, and seems to be increasing. It has been found also in the German territories adjoining Belgium in the neighborhood of Eupen. Energetic measures have been taken by the Belgium government in collaboration with that of France to protect the borders of the latter. The Pasteur Institute of Brussels, under the direction of Professor Jules Bordet, is actively engaged in elaborating a supply of antipest serum, and it will be interesting to learn of the efficacy of this serum, both prophylactic and therapeutic, in an epidemic of this nature which promises to be especially violent.

Monument to Edith Cavell.—A monument to the martyred Nurse Cavell was recently unveiled in Brussels in the presence of the members of the Royal family. The ceremony attracted a great concourse of spectators anxious thus to give evidence of their respect and admiration for this heroic victim of Germany's hate.

A Statue of Van Beneden.—At the Zoological Institute of Liége recently a statue was erected of the great biologist, Edouard Van Beneden. It will be remembered that it is to him that we owe a

description of several of the essential biological phenomena in fecundation—the penetration of the spermatozoon into the ovum, segmentation of the ovum, the fetal adnexa, the placentation of mammals, etc.

Retrogasserian Neurotomy.—At a recent meeting of the Royal Academy of Medicine of Brussels, Dr. De Beule of Louvain read a paper on retrogasserian neurotomy for the relief of rebellious facial neuralgia. This operation, due to the initiation of Krause, who performed gasserectomy, was revived by Spiller of Philadelphia and his colleague Frazier, who contented themselves with division of the sensory root of the ganglion. This operation did not give, however, the hoped-for results. It was the great neurologist of the University of Louvain, Professor Van Gehuchten, who perfected the technique of the operation, which is now practised by his pupil, De Beule. The posterior root of Gasser's ganglion is divided, corresponding to what Van Gehuchten called a "physiological exsection," with excellent results. The mortality of the operation is only 6½ per cent. in all cases, including those of new growths which had indirectly caused the neuralgia. As regards the serious ocular troubles (extensive ulcer of the cornea with leucoma, purulent destruction of the eyeball), they are much less frequent and much less grave than after the operation of gasserectomy, for Gasser's ganglion is preserved and the nourishment of the eye is thereby assured.

Death of Professor Nuel.—The death is announced at Liége of Dr. J. Nuel, formerly professor of ophthalmology and of the physiology of the organs of sense at the University of Liége. He was the author of numerous publications, among others a treatise on physiology in collaboration with Léon Frédéricq, professor of general and special physiology at the University of Liége.

3. The Frequency of Fractures. A Radiological Analysis of 1,226 Cases. C. R. Scott.
4. Multiple Serositis. William D. Reid.

1. Puerperal Sepsis and Its Treatment.—R. S. Titus, pointing out that there still exists more puerperal sepsis than there should be, and that the treatment of this condition, among many general practitioners, is not improving its mortality, gives the following summary of the subject: Puerperal infection is bacterial infection. Organisms gain entrance, first by vaginal examination; second, by the presence of an abnormal vaginal flora at the time of labor; third, by extension from foci of infection elsewhere in the body. The three types of puerperal infection depending upon the organisms are, first, hemolytic streptococcal infection; second, pyogenic infection; third, saprophytic infection. The treatment of each type depends upon the bacterial reaction and the knowledge of its pathology. By and large, leave it alone. The curette is dangerous. The antiseptic douche is unintelligent. The conservative treatment is rational and harmless. Surgery plays its part only when the infection has produced localized pus, and then the old-time surgical principle of the evacuation of pus obtains. Vaccines and serums have had their try and they have been found wanting. The future holds its hope first in aseptic preparation of the patient, absolute cleanliness of the operator. In this way, to lower the percentage of infection to its lowest possible point. Next, conservative treatment to do no harm rather than to go on the supposition that some good may come from interference and in the specific serum for each individual case based upon the success of the treatment of type four in pneumonia. Theoretically, vaginal smears and cultures of the pregnant woman taken soon before labor may point out those which contain harmful bacteria and in consequence some method of making these harmful bacteria harmless may be evolved.

4. Multiple Serositis.—William D. Reid bases this paper on an analysis of the cases of chronic multiple serositis that came to autopsy at the Massachusetts General Hospital, his object being to learn more of the disease, especially with regard to diagnosis. The cases are not listed as "multiple serositis" in the autopsy records, but he selected all cases in which the anatomical diagnosis contains the group of "chronic pleuritis, adhesive pericarditis, perihepatitis, and perisplenitis." His study was limited to cases in which this complete group is present in the record. There were fifteen such cases in the 3,900 autopsies studied, making the incidence of this disease just under .4 per cent. From this study he concluded that multiple serositis presents considerable diagnostic difficulty, particularly when other diseases coexist. Both history and symptoms may fail to suggest this condition. Presystolic murmurs and thrills may be heard over the cardiac apex in the absence of stenotic change of the mitral valve as disclosed at autopsy. Broadbent's sign and paradoxical pulse may both be absent. Ascites may or may not be present. A history of the recurrence of abdominal effusion over a long period, perhaps of years, should suggest chronic multiple serositis. The condition is probably due to the occurrence of an infection of a virulence sufficiently low to permit the survival of the patient and the healing of the inflammatory lesions by fibrous adhesions. The physiology of absorption from the peritoneal cavity as described by Clark, Buxton, and others offers further light on the development of chronic multiple serositis.

7. Medical Men in the American Revolution. (*To be concluded.*) Louis C. Duncan.

2. The Nature and Cause of Stammering.—Meyer Solomon briefly summarizes the nature and cause of stammering as follows: The stammerer suffers from nervous excitability and emotionality; this expresses itself, in the stammerer, in a speech disorder; the speech disorder in the stammerer is produced as the result of a definite series of phenomena, all of which are under the stammerer's control. First, there is the tendency on the stammerer's part to hurry, virtually to rush headlong and precipitately into speech expression of his thought. So great, so intense, so acute is this haste, that the stammerer really thinks faster than he can speak, and he endeavors to say immediately that which he has in mind. As a result of this, he throws his speech apparatus—either the articulative (for consonants) or vocal (for vowels) portion—into sudden, more or less, violent spasm. Respiratory spasm is commonly present in either case. In his blind rush the stammerer tries to pronounce a vowel (laryngeal sound) with his articulative organs—that is, while his speech apparatus is in the position for articulative (consonant) expression; or, he makes efforts to produce articulative sounds with his vocal (laryngeal) organs—that is, while his phonation apparatus is in action. As a consequence the stammerer either maintains a fixed articulative (consonant producing) position and endeavors, while in this position, to pronounce a vowel; or, he keeps his vocal (laryngeal) apparatus in continued action while battling to proceed hurriedly

and stubbornly to the pronunciation of a consonant. Both of these feats are impossibilities for any human being. In his insistence to accomplish this impossible feat the stammerer may bring into play much of his voluntary motor system and assume, during the act of speaking, various accessory or supporting attitudes and postures, spasmodic in nature, just as one would in hard work or fighting or running. The stammerer may become exhausted from his efforts. Finally, in despair or by compulsion, the stammerer gives up the useless struggle, relaxes the portion (articulative or vocal, as the case happens to be) of his speech apparatus which up to that moment has been in spasm, and only then, often to his great surprise, is he able to proceed to the pronunciation of the next sound.

6. Disturbances of the Heart and Liver Caused by Low Grades of Astigmatism.—E. L. Jones emphasizes that any and all astigmatism must be corrected to the finest degree possible as to strength and axis of cylinder, else the small error remaining for the eye to overcome will still permit the continuance of symptoms. This does not mean that the other source of refractive eyestrain, hyperopia, does not play its part and need correction, neither does it mean that myopia, which is not a source of refractive eyestrain, is not to be reckoned with. But associated with myopia and hyperopia of all degrees, and in cases of supposedly noncorrectible irregular refraction, there is usually more or less astigmatism, at times very difficult to establish as to exact amount and axis. He also emphasizes his belief that more people suffer from the eyes than with the eyes, and expresses the hope that the day will come when every patient affected with a persistent vertigo, pain or drawing in the neck or shoulders, unexplainable general fatigue, nervous depression, gas in stomach, cardiac asthenia, or cold, clammy feet, will be referred to the most painstaking oculist available.

9. A Second Attack of Meningitis After an Interval of Eighteen Months. William Allan.

2. Ocular Symptoms in Exophthalmic Goiter.—J. H. Claiborne gives as the purpose of this contribution to set forth the signs present in exophthalmic goiter; to give what apears to be a simple, obvious and reasonable explanation of the great majority of them; to remove a certain amount of confusion which exists generally; and to describe what appears to be several signs which have not been heretofore remarked. His discussion of the subject is summarized as follows: 1. Exophthalmos, or proptosis, is the first and basal sign of exophthalmic goiter. The majority of the other signs follow sequentially. The order in which the most prominent ones should be mentioned is: exophthalmos, Dalrymple's sign, Graefe's sign, Stellwag's sign. 2. In the Dalrymple sign the sclera shows above and below the cornea and more markedly and frequently below than above. It may be absent above but present below, or vice versa. It is distinctly a sign observed in a condition of rest in the primary position of the eye. 3. The Graefe sign is seen only in motion from above downward, and is more marked in all cases in movements below the horizontal meridian. In order to demonstrate this sign, the eye should be made to move *very slowly* from above downward. 4. The pupils are as a rule larger than normal in exaggerated cases; and this sign is more marked in blonds than in brunettes. 5. Trembling of the upper lid sometimes occurs without closure of the lid. The sign exophthalmos, taken in conjunction with goiter in the neck, tachycardia, and the nervous and psychopathic symptoms which go with these signs, form a picture that constitutes the entity known as Parry's disease, Graves' disease, Basedow's disease, and exophthalmic goiter—the most marked and dramatic disease in the realm of medicine.

3. Three Pertinent Questions on Maternal Feeding.—W. A. Mulherin. See MEDICAL RECORD, May 15, p. 847.

4. Frequency of Syphilis with Cancer of the Lips, Tongue and Buccal Mucous Membrane.—N. Austin Cary gives a series of tables compiled from 907 case histories in the record files of the Surgical Pathology Laboratory of the Johns Hopkins Hospital, the material being drawn from that hospital, the clinic of Dr. Joseph C. Bloodgood at St. Agnes Hospital, and from various other sources. The series does not represent selected cases. Cases are classed as positive when either a positive Wassermann test or reasonable evidence of syphilis in the past history was found. Of the 907 mouth lesions 771 were malignant and 136 benign. Of all the cancer cases, only three occurred in the white female, and in none of these could syphilis be proved as an etiologic factor. No cases of cancer were observed in the black female and only two in the black male, in spite of a very considerable proportion of negro patients in Baltimore clinics. The writer considers this fact of special interest in view of the well-known prevalence of syphilitic infection in this race. It was found, among other things, that syphilis in association with cancer of the tongue is approximately three times more common than in association with cancer in other locations about the mouth—14.5 per cent., or about one in seven. He considers this fact urgent reason against protracted antisyphilitic treatment in tongue lesions which may be cancer, even in the presence of positive evidence of syphilis. Regardless of the causal relationship established the prognosis is that of cancer and not of syphilis, and treating the syphilis will not affect the cancer, but will only delay urgently needed surgery.

2. An Investigation of Gastric Function by Means of the Fractional Test-Meal.—John A. Ryle reports results up to date of investigations being carried on on an extended scale regarding this method as a means of studying normal gastric physiology and as an aid to clinical diagnosis. He gives an abridged account of the technique; reproductions of specimen charts illustrating physiological and pathological phenomena; a summary of the advantages of the fractional method of gastric analysis.

5. A Plea for Simple Anatomical Names.—William Cuthbert Morton points out that he is not pleading for a particular code, nor for particular names, but for the one guiding principle of simplicity based on the free use of the national language. He states some of the outstanding principles and illustrates their application by a few examples. The writer, the student, the teacher, and the patient would profit by this simplification of anatomical terminology. It would greatly "facilitate the progress of study," by removing much of the "rubbish that obstructs the journey." Anatomy is among the most precise of sciences. Why should she not lead the way in the science of terminology?

1. Healing of End-to-End Intestinal Anastomosis with Especial Reference to the Regeneration of Blood Vessels.—Florence R. Sabin, following the suggestion of Professor W. S. Halsted, in relation to the study of methods of end-to-end anastomosis of the intestine which he and Dr. Mall had made in 1887, made the application of some of the improved methods in connection with vascular injections, as applied to the healing of blood vessels in these anastomoses. It was thought that some light might thus be thrown on the general problems involved in the healing of intestinal wounds. As in the original experiments of Halsted and Mall, dogs were used in these experiments, the series studied comprising 25 dogs, of which 20 were injected, involving 27 anastomoses. From these studies, which are illustrated by twenty-four plates, it was shown that in the end-to-end anastomosis of intestine the infolding of the wall does not produce any blocking of the lumen, that the infolded parts are viable, and that the mucosa continues to function in absorption, but that there is a very great increase in the number of cells secreting mucus. Ultimately this change in functional adaptation is brought back to the normal by the death of the mucus cells and the regeneration of the mucosa. Wherever the muscularis mucosæ is cut or ruptured without the occurrence of an infection, the glands of the mucosa invade the submucosa, often forming cysts there, but these glands are subsequently restored to the mucosa by the regeneration of the muscularis mucosæ, which makes a barrier for the glands. For the smooth muscle, the histological technique shows that its cells are very sensitive to injury and that it is hardly possible to put a clamp on smooth muscle without producing changes that can be recognized under the microscope. It seems very important to the writer that this series of end-to-end anastomoses produced no dilatation of the wall of the intestine and hence no damage to the musculature sufficient to make it thin out. All of the cases show gaps in the musculature where the stitches pull through, but though this damage is inevitable, the fact that the muscle in syncytial, and that the stitches are limited to six points around the lumen of the gut, seems to limit the amount of destruction to the musculature more than in the end-to-side form of the operation. In the regeneration of the vascular system it has been shown that the regeneration of the vessels is limited to specific areas where the growth of new vessels is preceded by a change in the endothelium of the old vessels which may be characterized as a return of the endothelium to the original angioblastic type involving a very great multiplication of the endothelial nuclei, and from these transformed vessels solid masses of angioblasts like those of the embryo grow out, acquire a lumen, as in the embryo, through liquefaction of the cytoplasm, and become new vessels, first capillaries, then arteries and veins.

2. End-to-End Anastomosis of the Intestine by Presection Sutures.—Emile Holman, who performed the surgical work in connection with the experimental observations by Dr. Sabin (*vide supra*), emphasizes the following points concerning this form of suture: 1. All sutures are applied before incision into the bowel, regardless of the amount of bowel to be resected. The value of this is evident from the point of view of asepsis and from the standpoint of facility in introducing sutures before division of the intestine. 2. All sutures are applied without entering the lumen and without handling the septic mucosa at any time. The method has been applied in the large bowel and in several end-to-side anastomoses in the cecum with excellent results and without subsequent infection. 3. The sutures are applied at right angles to the lumen of the bowel and therefore parallel to the large vessels coursing through the bowel wall. Accordingly, none of the larger vessels are constricted when these sutures are tied, and, as shown by the injections, there is not the slightest impairment of circulation to the severed end of the various intestinal layers. The villi of the mucosa continue to function to the very edge of the divided bowel. There was no evidence in a single specimen of sloughing of the inturned edges, ideal and rapid healing at the point of union being thus provided for. 4. In the entire series there was no evidence of dilatation proximal to the anastomosis, thus indicating the absence of any obstructive narrowing of the lumen of the bowel. If this is true for the intestine of the dog with its small lumen, no such difficulty need be expected in the intestine of the human subject with its larger lumen. There is a minimum of trauma such as accompanies the use of mechanical devices, or the handling of the bowel edges with forceps as in the plain end-to-end and Connell sutures, in all of which injury to the mucosa is quite unavoidable.

Colored Audition.—Ribon of Bogota, Colombia, S. A., who has published an article on chromacousia or colored audition, received a letter from a reader which outlines his personal case; this letter he sends to *El Siglo*, which publishes it as an original article. The patient at first attached no importance to the phenomenon. Fifteen years before he had become totally blind from disease of the optic nerves and from the very onset of his blindness he noted that certain sounds produced visual effects. For example, the first bars of Gounod's *Ave Maria* called forth a color hard to define—a sort of mixture of violet and rose. This appeared only as a haze without definition. On certain occasions he beheld an emerald green on hearing the violin. Commenting in this case Ribon states that chromacousia is seen in Colombia under exceptional circumstances. He himself knows of a subject who sees blue under the influence of certain musical airs of which he does not know the names; he never pays much attention to the phenomenon. The color seen by the blind correspondent on hearing Gounod's air is doubtless light violet, for that is the shade, along with blue, which Gounod's music usually produces in the subject predisposed to chromacousia. The author has written on the psycho-optic and psycho-auditive centers and in this study had already published the fact that the music of this composer aroused a sense of either violet or turquoise blue. There is no doubt that a concerted effort by ophthalmologists, otologists, psychiatrists, etc., would bring to light many facts in connection with chromacousia, a phenomenon not usually associated with blindness and perhaps in the latter case having a somewhat different motivation.

Fatigue.—Laumonnier reviews the recent work on this subject by Mme. Ioteyko, upon which subject she has proved herself one of the world's greatest authorities. Experimental and occupational fatigue are both concerned. Fatigue is so universal a condition that it is seen in the inorganic world and metals when tested for torsion, etc., may exhibit fatigue states. But this form, which is purely a question of physics and molecular activity, is not closely related to fatigue in living beings. As a matter of fact there is nothing to correspond to fatigue in the vegetable kingdom (with the single exception that in experiment the so-called "sensitives" can be exhausted). Of protozoa in the free state the same may be said and we can actually induce exhaustion in cultures of protozoa, yeasts, and bacteria by rendering conditions sufficiently artificial. Here fatigue and vitality appear to be the same thing, which is not true necessarily of mankind, in some of whom exhaustibility may be extreme, yet with great tenacity of life. But it is not certain that fatigue always connotes exhaustion, for we cannot be sure that the phenomenon has not a component of inhibition. In the protozoa, for example, the conditions under which fatigue can be made

to appear are evidently those which favor inhibition. Fatigue is chiefly a phenomenon of the higher metazoa in which within a closed sac there is a circulatory system and fluids of a composition nearly constant. This necessitates elimination of waste products by certain organs adapted for the purpose. Accumulation of a certain amount of such products means fatigue. The need for sleep is best explained on this ground, that cerebral activity is periodically inhibited until this excess is gotten rid of.

Physiological and Pathological "Ringers."—Frenkel writes of certain counterparts in physiological and pathological syndromes, using the word "socie," which may be rendered by the slang term "ringer" (first used in connection with trotting races in which one horse was substituted for another which it strongly resembled). The author divides these into two groups, in one of which the exaggeration of a physiological syndrome simulates a disease, while in the other two pathological conditions having little in common may outwardly resemble each other. Under the first head the continuous evolution of symptomatology of the objective or measurable type promises that it will be well represented in the future. As an example take the case of the "sign of Musset," a physiological behavior dependent on the elasticity of the vascular walls, which closely resembles a pathological cardiac arrhythmia. The method of graphics enables us to illuminate this resemblance. So the protodiastolic *bruit de galop* may not represent a diseased state but only an exaggeration of the so-called "third sound of the heart." Mickulicz's disease of the lacrymal and salivary glands has its physiological analogue and the author has doubts that it is really a diseased condition at all. Anisocoria as is well known may be purely physiological, and the author finds many other simulations of the same type in ophthalmology. In regard to the other form he mentions meningeal reactions which closely simulate one another yet which are found to depend on very different basic conditions.

Biochemistry in the French University of Strassburg.—Nicloux delivered the opening lecture on the chair of medical chemistry at this university, which chair was originally inaugurated in 1870, just in advance of the war which lost the college to the Germans. The original chair of chemistry had been initiated in 1794, and largely as a result of the pioneer work of Lavoisier between 1772-1786. The old faculty professors down to 1870 were not so well known, although Cailliot, the last incumbent, was said to have been a remarkable chemist. Driven out of the city by the German conquest he moved to Paris and attached himself to the laboratory of his old pupil Wurtz, where he continued his valuable studies on the terebenthines and allied substances. The German incumbents were Hoppe-Seyler until 1895, and Hofmeister until the school passed back to the French. The lecturer then passed to the careers of two great French biochemists, Wurtz and Schützenberger, whose names suggest their Alsatian origin. Both men were born in Strassburg. Wurtz, born in 1817, was a resident of the city until 1843, studying under Cailliot and later under Liebig. At Paris he succeeded Dumas as faculty professor of medical chemistry. In 1874 he organized the chair of organic chemistry at the Sorbonne. Schützenberger, also a pupil of Cailliot and later his assistant, remained in his native city until after the war, after which he became professor in the Paris School of Industrial Chemistry. Had it not been for the German occupation he would doubtless have succeeded Cailliot in the Alsatian University. The leading activities of Wurtz were directed to hypophosphorous acid, the cyanogen compounds, the compound ammonias and ureas, carbides having mixed radicals, mono- and polyatomic alcohols and other important aspects of organic chemistry while his colleague is best known for his work on alkaloids, compounds of acetic acid with carbohydrates, platinum compounds, the rare earths, etc., and in the industrial world sodium hydrosulphite —the powerful reducing agent—indigo, etc. His labors on cleavage products of albumins must also be mentioned.

Angina Vincentii.—Voss of the Epidemic Hospital at Ullevaal, says that he sees from 3 to 5 cases of this malady annually but during the last 4 months there have been 16 new cases. The associated germs which cause it were first described by Miller in 1882 but in ulcerative stomatitis. Of the 16 patients all but one were men and the age period was 17-23. The ulcero-membranous and diphtheroid forms are recognized, the latter being much less common and at the same time, despite its name, much milder, running its course in about a week, while the severer form may persist for months. The truth of these assertions was upheld at the authors' clinic, for all the cases were ulcerous. The general reaction is very mild, but there may be severe pain in the throat. On inspection one sees one or both tonsils swollen but this is not inevitable and there may be no swelling anywhere. In these negative cases like the others there will be a membrane on the tonsils in the diphtheroid cases, which when detached leaves a bleeding surface which soon reproduces a new membrane. The ulcerous form may be distinguished by the presence of one or a number of ulcers in various localities, usually below the level of the tonsil, but at times on the soft palate and uvula, the tonsil and gums. In regard to infection at a distance both nephritis and endocarditis have been seen rarely and apparently not of a severe type. The odor of the breath will alone enable an expert to make the diagnosis, but for routine diagnosis and differential diagnosis smears and cultures must be made. The salvarsan treatment proved to be absolutely specific and it does not appear that the injection method is necessary, for the local application of the dry powder or 2 per cent. glycerin solution answered the purpose. Neosalvarsan was not so efficient.

May-June, 1920, lxii, 5-6.

Wound Diphtheria.—Von Wendt and Wallgren report two cases of wound diphtheria which occurred in the same clinic at the same time. One subject was a wounded veteran of the war, who had submitted to an operation for an aneurysm for which a ligation had been done in the continuity of the right leg. Three weeks later the appearance of the operation wound suggested a probable hospital gangrene. The other case was an appendicitis operation which was complicated by peritonitis at the time; the wound made by the operation had first enlarged and then ulcerated. The first case was complicated by severe toxemia as shown by cardiac weakness, heavy albuminuria and disturbances of accommodation, while in the other there was no notable constitutional reaction. Both cases showed the diphtheria bacillus, streptococci and staphylococci, proteus and various anerobic obligates and the finds were strikingly alike. The first case was accepted as it stood, but in the second by reason of the absence of general reaction animal experiments were made and inoculation of guinea pigs gave positive results. Local measures were inert until Dakin's solution was tested and this had a marvelous result on not only the local, but the general symptoms of the first subject. The solution was applied to the wound by the well known Carrel's method.

Late Result of a Bone Transplantation.—Faltin reports the case of a subject who as a result of an osteochondroma submitted to a resection in the upper portion of the fibula. A piece of the tibia of the opposite side 9 cm. in length was removed and implanted in the osseous defect and healed in properly. Six years later there was a reexamination. The *x*-ray showed dense bony tissue at the seat of the transplant, the structure of which shaded into the fibula without sharp transition. The result, the author says, was approximately perfect.

Book Reviews.

RAMBLING RECOLLECTIONS. An Autobiography. By A. D. ROCKWELL, M.D. New York: Paul B. Hoeber, 1920.

IT has been said that the autobiography of anyone—poet or peasant, saint or sinner, millionaire or pauper—if honest, could not fail to be interesting, as a human document at least. This is to be accepted with reservations, for not every one is humble enough and simple enough, or even with enough sense of humor, to reveal himself satisfactorily to the world. But no such reservations apply to this book. It is written so simply and honestly and, although an autobiography, is so free from any offensive personal note, that it gives pleasure from the first page to the last. Dr. Rockwell was the son of a school teacher and was born in New Canaan, Conn., in 1840. His boyhood was passed in western Connecticut, but he was sent to Ohio for his college education, Kenyon being the institution chosen, for religious reasons, by his father. His medical education was begun in the office of a physician in Milan, Ohio, continued in Ann Arbor, and completed—at least up to the stage of graduation—at Bellevue Hospital Medical College, New York. Upon graduation he entered the army and served as surgeon to the close of the Civil War. He then returned to New York and attended a course of lectures in the College of Physicians and Surgeons. After a brief experience in general practice Dr. Rockwell became a partner of Dr. George M. Beard, his career from that time on being well known to New York physicians, among whom he was one of the first electrotherapeutists, doing much to raise that branch of science out of the disrepute in which it lay for so long a time.

In the list of well-known men whose paths were for a time collinear with Dr. Rockwell's may be mentioned General Sheridan, Austin Flint, Salmon P. Chase, Edwin M. Stanton, John Jay, Mark Twain, General Sherman, and Commodore Vanderbilt.

To Dr. Rockwell's many friends and acquaintances this autobiography will of course be intensely interesting, but even those who have not the good fortune of a personal acquaintance with the author will find this real history of a doctor's life far more entertaining than many a book avowedly designed for entertainment.

THE DAWN OF MODERN MEDICINE. An Account of the Revival of the Science and Art of Medicine which took place in Western Europe during the latter half of the Eighteenth Century and the first part of the Nineteenth. By ALBERT H. BUCK, B.A., M.D., Formerly Clinical Professor of Diseases of the Ear, Columbia University, New York; Consulting Aural Surgeon, New York Eye and Ear Infirmary, etc. New Haven: Yale University Press; London: Humphrey Milford, Oxford University Press, 1920.

THIS volume is a continuation of Dr. Buck's former work on "The Growth of Medicine." Readers of that book will welcome the present volume; and that large class of physicians to whom the History of Medicine is almost a sealed book will find this new work a most delightful introduction to a fascinating subject. The period covered by this volume contains names which are familiar to all educated people; and the novice will feel that he is not confronted with mere names which belong to a period so remote as to be negligible. Thus, to select merely a few instances, the reader of this volume will find an interesting account of Laennec and the introduction of the modern method of auscultation; of homœopathy and some of the reasons why it obtained a footing; of Percival Pott and his description of the disease which goes by his name; of the brothers Sir Charles and John Bell, and their work in anatomy and surgery; and of Bichat and his investigations in anatomy and physiology. Other names which adorn this period are Abernethy, Astley Cooper, Lavoisier, von Haller, Magendie, Larrey. Of all of these and of many others, Doctor Buck gives us, not a complete history, but a brief and graphic account of the main facts of their career; and the story is told in such an interesting way that the reader is likely to venture on some larger work for further information. The greater part of the work deals with Medicine and Surgery in Switzerland, Germany, Italy, England, and France during the period mentioned on the title page; there are also chapters on Smallpox, on Broussais and Broussaism, and on Hospitals and Teaching Organizations. The book is well printed and profusely illustrated; and the author is to be congratulated on having produced a most attractive and readable work on the history of medicine.

THE NEWER METHODS OF BLOOD AND URINE CHEMISTRY. By R. B. H. GRADWOHL, M.D., Director of the Gradwohl Laboratories, Chicago and St. Louis; Director of the Pasteur Institute of St. Louis; and A. J. BLAIVAS, formerly Assistant in Same; formerly Assistant in Chemical Laboratory, St. Luke's Hospital, New York City. Second Edition. With seventy-five illustrations and four color plates. St. Louis: C. V. Mosby Company, 1920.

WE are glad to note that the reception accorded the first edition of this work has been such as to warrant the preparation of a second edition. The increasing interest in the chemistry of the blood is shown by the fact that a number of methods and changes in technique, newly introduced since the publication of the first edition three years ago, have been incorporated in this revision. The authors still adhere to their plan of giving, as a rule, only one method for each test. This is perhaps better if the book is to be used only as a guide for beginners in this branch of laboratory work, and also serves to limit the size of the book, keeping it within the dimensions of a convenient manual; but professional analysts and advanced laboratory workers would need a book giving details of all the methods and techniques of proved value.

ANATOMIE DES MENSCHLICHEN GEHIRMS UND RÜCKEMARKS AUF MYELOGENETISCHER GRUNDLAGE. Von PAUL FLECHSIG. Erster Band. Leipzig: Georg Thieme, 1920.

THIS volume is practically an atlas, having but 48 pages of text aside from the descriptions of the plates which are very full. The plates number 25, each comprising a number of sections of the brain or histological figures, the total being well above a hundred exclusive of a number of text figures. The textual or first part of the volume deals with myelogenesis as a method of research, myelogenetic cortical fields and the relations of myelogenesis to pathology. The bibliography comprises 49 references to works of the author alone, of which the volume represents the summation. These extend from 1872 to date. The author published his celebrated studies of the cortex in the 80's and 90's of the last century with special reference to association centers.

A TEXT-BOOK OF OPHTHALMIC OPERATIONS By HAROLD GRIMSDALE, M.B., F.R.C.S., Ophthalmic Surgeon and Lecturer on Ophthalmic Surgery to St. George's Hospital, Surgeon to the Royal Westminster Ophthalmic Hospital, and ELMORE BREMERTON, F.R.C.S., Consulting Ophthalmic Surgeon to the Metropolitan Hospital, Surgeon to the Royal Westminster Hospital. Second Edition. New York: William Wood and Company, 1920.

THE expressed object of the authors is to give the student, in outline, the chief ways in which the various problems have been attacked, and to leave him to adapt some one of them to his varying requirements. In this second edition they have not found it necessary to deviate very much from the lines originally laid down. The order of chapters, based on the order in which they found it convenient to proceed when teaching the subject to students, has been retained almost unchanged, and includes, in sequence, operations on muscles, for ptosis, on the lids (two chapters), on the conjunctiva; enucleation and its substitutes; operations on the lacrymal apparatus and bones of the orbit; cataract; after-cataract; the operative treatment of glaucoma; some operations on the cornea, sclerotic, and iris; foreign bodies in the eye. It is manifestly impossible, in a book of 427 pages of text, to give descriptions of all ophthalmic operations, or to make such a selection of operative procedures as would meet the approval of all readers. The concern of the authors with the classification more than with the examples chosen to illustrate it, seems to find justification.

Society Reports.

AMERICAN THERAPEUTIC SOCIETY.

Twenty-first Annual Meeting, Held in Philadelphia, May 7 and 8, 1920.

(*Concluded from page* 538.)

The Interrelationship of Tonsillar Infections and Their Bearing on Treatment.—Dr. HARRY B. ANDERSON of Toronto, Canada, read this paper. (See page 589).

The Anatomy and Physiology of the Tonsillar Structures in Relation to Cryptogenic Infections.—Dr. GEORGE B. WOOD of Philadelphia presented this communication. (See page 593).

Dr. SPENCER L. DAWES of New York said that he wanted to compliment Dr. Wood on the study he had made and the beautiful microscopical work which he had shown. He had never seen, during 30 years of practice, any more beautiful and illuminating display of slides.

Dr. CHARLES E. DE M. SAJOUS of Philadelphia, after expressing his appreciation of the work of Dr. Anderson and also of the study of the physiology of the tonsils by Dr. George B. Wood, stated that for some years he had been investigating the relation between the ductless glands and influenza. Recently—very unfortunately only after the pandemic of 1898 and the recent epidemic—he had been able to obtain some light in this direction. He felt that here lay the fundamental explanation of this fell disease. As to the relation between the pathology of influenza and the tonsils there existed a connection of great importance. He had traced the bacteriology of Pfeiffer's bacillus throughout the respiratory channels—the nose, nasopharynx, and tonsils, and the lymph channels along the respiratory tract and bronchioles. It was only when the pulmonary alveoli were reached that he had struck what he regards as the keynote of the disease. Here he had found conditions similar to those which in the laboratory made it possible to cultivate the Pfeiffer bacillus —hemoglobin, oxygen, and elevated temperature. In respect to the tonsils, the salient feature to bear in mind was the all-important role of the defensive barrier afforded by the upper respiratory tract. If the Pfeiffer bacillus was able to reach the pulmonary alveoli after running the gauntlet of its defenses, and also those in the bronchial tree—phagocytic, epithelial, and mucoid—then only did infection occur. The alveoli then became the seat of what the speaker termed a "necrotic alveolitis," a condition which was special to the disease, and which pathologists had recognized as such. The role of the tonsils and of the lymphoid structures of the nasopharynx could be compared to that of a ring of forts through which the air contaminated with Pfeiffer bacillus had first to pass. Tyndall had shown, in fact, that contaminated air, after passing through the nasopharyngeal area was perfectly sterilized. Such being the case the prevailing tendency to remove the tonsils promiscuously would seem to involve risks. Their identity as participants in the protective mechanism should be considered. Efforts might be made to treat them actively if need be, but at the same time, preserving, as was done in thyroidectomy, what portions of the parenchyma were still able to carry on the glandular protective functions.

Dr. A. E. ROUSSEL of Philadelphia said that he thought the tendency to-day was to sacrifice fewer tonsils. This paper brought up a question as to the value of tonsil surgery. Dr. Packard, about 25 years ago, pointed out that endocarditis not infrequently followed acute tonsillitis. That was the first work on focal infection. The chronically infected tonsil contributed a good deal to ill health. Often a persistent albuminuria was associated with such cases. Patients were frequently discharged after an attack of acute tonsillitis, the albuminuria having passed away for the time being onyl, and later a chronic kidney condition was found. This albuminuria was not physiological, but it showed a relative weakness. In studies he had made on some young men of a winning boat crew a slight albuminuria was observed in several cases after return from a race. The career of these men was followed and in later life a larger percentage than one would expect died of kidney disease. Acute virulent streptococcic infections were interesting. Forms of tonsillar and peritonsillar infection showed a remarkable degree of persistency and some cases developed endocarditis.

Dr. N. P. BARNES of Washington, D. C., said that he would like to call attention to the enormous amount of work Dr. Anderson had done. Arthritis and endocarditis were common sequelæ of tonsil infection. Several points need especial emphasis in this subject. During the periods of the year when people lived out of doors, they breathed better air and had better health, thus being able to live above their infections. During the winter months there was less ventilation of the homes, resulting in lowering of vitality. Consequently, there was an increased percentage succumbing to infections. Arthritis and constitutional disorders were more prevalent at that time. The cases that did not succumb to the acute exacerbation, went on to swell the numbers of creaking and enlarged joints, lame backs, and cardiovascular changes of old age. The mucous membranes of the throat should be treated kindly. In some families a sore throat was treated with everything from iodine to kerosene. This not only removed the protecting mucus and left a highly sensitive, reddened mucosa, but actually injured the membrane and lessened its ability to resist infection. In some laboratory work done on tonsillitis, it had been recognized that when the tonsil was removed during an attack of tonsillitis, there was found a high percentage of organisms, mostly streptococci. If the operation was postponed until later, the tonsil infection was not so pronounced. The argument would seem to be to eradicate the tonsil before the infection got through to the joints or the heart. The infection often appeared in the joints in from ten days to two weeks after the tonsillar infection. Absolute enucleation of the tonsil was necessary. Tonsillotomy was of no benefit as it left a submerged, buried form of infection. The entire capsule must be removed.

Dr. GOODMAN of Brooklyn asked if there was any anatomical or etiological connection between the tonsils and the hypophysics.

Dr. THOMAS F. REILLY of New York said he had been sceptical as to the value of removal of the tonsils till last winter when he saw a case of myasthenia gravis in which there was no history of focal infection except in the tonsils. After transfusion the tonsils were removed and the boy's whole aspect changed. He had seen other cases, but not so marked. This was very strong evidence that the tonsils were foci of infection. He would like to know if Dr. Wood considered it bad policy to do surgery during the attack. The surgeon could remove a large portion in acute inflammation. Did that do the patient any real harm? This had not been discussed. It would be bad surgery in other parts of the body. Another point was whether the infection might not be due to blood stream infection rather than to local or focal infection. Perhaps the streptococci of a particular strain might have a chemotactic effect in the tonsils just as some strains had for the gall bladder and gastrointestinal tract. Perhaps they got into the glood first, reached the tonsils and then got back to the lymphatics. Many infections began that way in the lung, peripherally first, and then worked back from the lung and hylus to the lymphatics. Would Dr. Wood discuss that paradox?

Dr. ANDERSON, in closing, said that he wished to add his appreciation of Dr. Wood's paper, to that of the other members. It was a very comprehensive paper. His own point of view was that of the clinician. He was glad to have heard this splendid description of the anatomy and physiology of the tonsil. In regard to Dr. Roussel's remarks about albuminuria there was probably a persistence of local infection which was the original cause of the trouble. If such infection was left sealed up in the tonsil it meant a progressive renal condition. If the infection was removed the case might progress to cure.

Dr. WOOD, in closing, said that it was difficult to appreciate the amount of work that Dr. Anderson had done in getting the material ready for this paper unless one had had experience in this type of bacteriological study. From the comparatively few number of tonsils that Dr. Wood had himself examined bacteriologically he could understand something of the time

and patience required when hundreds of cases were cultured and a differential diagnosis made as to the infecting organism. However, in spite of all this work, Dr. Wood felt that, at present, our knowledge of tonsillar infection was far from being absolute and that the only positive way to determine whether or not a tonsil was the source of a cryptogenic infection was the removal of the suspected tonsil or tosils. In his own experience he has sometimes found that the most vicious tonsils would prove to be innocent while the innocent looking tonsils would occasionally prove to be most vicious. However, except for the discomfort and slight risk of the operation the removal of the tonsils when properly done was an absolutely harmless procedure, and their absence could in no way have any deleterious effect on the patient. According to the best of his knowledge there was no connection between the pharyngeal tonsil and the typophysis. It was against all surgical principles to operate on tonsils during an acute attack but in one case in which he was forced to operate on account of dyspnea, there was no excess of bleeding and even though a tracheotomy had to be done a few hours after the operation the patient made an absolute normal recovery. Dr. Wood did not believe in blood infection of the tonsils but could conceive that in a general bacteriosis they might be involved as could any organ of the body.

The Therapeutics of Benzosulphinide.—Dr. REYNOLD WEBB WILCOX of New York read this paper (see page 595).

Dr. JACOB DINER of New York said that people were accustomed to take four or five lumps of sugar, which was the same as an alcohol derivative, and produced a systemic effect. Benzosulphinide might be used with better advantage to the health.

Dr. WILCOX said that this subject had come before the New York courts and he had been called upon to give testimony. This action finally reached the Court of Appeals in the State of New York and the decision was based upon the fact that benzosulphinide was harmless. He was a member of the Revision Committee of the Pharmacopœia and was responsible for the drug coming into the Pharmacopœia as an antiseptic. The anticeptic properties were, however, not particularly marked. Various boards of health had made an officious ruling against the use of this substance, but they were offset by the decision of the Federal and State courts wherever the scientific facts had been considered.

Third Session—Saturday Morning, May 8.

DR. H. B. ANDERSON, VICE-PRESIDENT, IN THE CHAIR.

A New Procedure to Prevent Spinal Puncture Headaches.—Dr. GUSTAV BAAR of Portland, Ore., presented this communication, which, in his absence, was read by Dr. Anders of Philadelphia. (See page 598.)

Dr. JOHN C. HEMMETER of Baltimore said that he wished to congratulate the society on this very interesting paper, by one who was apparently an able and careful clinician, with conservative and critical judgment. The hydrostatic explanation of the headache was given. The brain floated, it did not rest anywhere on the bony cavity, and when fluid was withdrawn the twelve pairs of cranial nerves rested on the bottom of the cavity with production of pressure. The use of saline solution to replace fluid had its foundation in this fact. There was a rapid osmosis which put the watery cushion back and removed the pressure.

Dr. J. M. ANDERS of Philadelphia said this theory seemed to be quite a plausible one. Those who had had long experience with spinal puncture work were familiar with these headaches and would welcome any method for overcoming them. The method seemed to be founded on a rational basis. It should lead them to make further observations in the same direction and if the work were corroborated it would seem to be a step in advance.

Dr. HENRY BEATES of Philadelphia said that intracranial blood pressure was regulated by the innervation of the trisplanchnic area. The headaches were caused by disturbance of the intraabdominal circulation resulting in relative intracranial ischemia. It had been his practice to treat these headaches with full doses of digitalis. In "Katzenjammer" there was trisplanchnic venous passive congestion and the resultant cerebral ischemia. Full doses of this drug would prevent the headache. In spinal puncture headache, preceding the operation, one could give one-fourth to one-half a grain digitalin, or two to four c.c. digitalin. The former, in 10 c.c. of physiological salt solution hypodermically, would arrest the symptoms. The mechanical effect of posture in ameliorating this type of headache and the physiological prevention with digitalis therapy, could be explained practically in a similar manner—an intracranial circulatory equilibrium was maintained and results thereby secured.

Dr. JACOB DINER of New York said that in the paper it was stated that a 5 per cent. solution of sodium chloride was used. That needed verification. He thought there was a typographical error and the author meant 0.5 per cent. On two occasions he had seen 1/5 per cent. used, and it was attended with serious results.

Dr. J. C. HEMMETER said that the author meant 0.5 per cent. This was an error in the typewriting.

Intestinal Infection with Lamblia Duodenalis.—Dr. JOHN C. HEMMETER of Baltimore made this presentation. He said that this organism was at present also known by the name of "Giardia." The organism had been observed and classified under many names, which had led to some confusion. Dr. Hemmeter had observed the first case reported in America, and since then two cases had been seen in the practice of a Baltimore physician. The case observed by the speaker was in a male child of three years, born in Crisfield, Md., of healthy parents, but the child had suffered abdominal pain and distention since birth. The parasite, a flagellate protozoan, was very common in the upper part of the small intestine of the ordinary house mouse, the brown and the black rat, and the field mouse; it occurred also in domestic cats, dogs, sheep, rabbits and guinea pigs. Man became infected by eating food soiled by mouse excreta containing the encysted stage of the organism. Children probably became infected by being left to crawl about on floors accessible to the animals referred to. The parasite attached itself by means of the sucker, to parts of the duodenum and jejunum, and in severe cases it occurred in the ileum. In diarrheal cases the organism was not found encysted, and freely motile forms were found in the stools. The stool had to be observed warm, to note the motility of the parasite. The parasite probably occurred more commonly than was supposed, because systematic stool examinations were infrequently practised, and also because the usual diarrhea and dysentery remedies were destructive to the parasite. Tannic acid derivatives destroyed it. These remedies could not be given to children, however, in sufficient strength to destroy the parasite. In all cases of diarrhea in children with offensive stools the feces ought to be examined for this organism. The creature attached itself to the small intestine by suction. Observed in warm stools the movements, by means of the flagella, were surprisingly rapid. Its nutrition was by osmosis. It was hard to tell how long individuals had been infected with the parasite, as cases were found infected by millions without exhibiting any clinical symptoms. It was observed that the stools of patients infected were enormously increased in bulk when there was no diarrhea. This was due to two facts, first, the parasites might multiply so enormously that they increased the bulk of the stool; secondly, they might cover absorptive epithelium so completely that food could not be absorbed and reduced in bulk. The acidosis, sometimes observed, was probably due to slow starvation. The organism was usually associated with other intestinal parasites. Although lambiliasis was not so serious as amebiasis, it should not be taken too lightly, for even if the individual was not seriously ill he might become so if not treated. The most effective therapeutic agent was found to be hexamethylenamine tetranime, which rendered the bile sterile. In children the dosage should be graduated according to age and weight. One grain of the above with ½ grain of salol, three times a day, in a child of three years, cleared the intestine within ten days. It would seem advisable to give radium and the *x*-ray a trial, as this would weaken the parasite, which could then be expelled by castor oil. It was important to maintain the nutrition of the patient during treatment. The introduction of methylene blue through a duodenal lavage tube was an effective

form of treatment. Colon irrigations could also be used. When there was associated amebiasis, emetine should be given. In any case treatment should be instituted and persisted in, as continued lambliasis had been known to cause perforation and death.

Dr. N. P. BARNES of Washington asked if ipecac would have any effect on the organism.

Dr. HEMMETER said that these infections were always double, *Ameba hemolytica* were always present with *Giardia*. Emetine had an effect in hypodermic injections on the amebiasis, not on the lambliasis. The patient usually improved and one thought him cured, but there were cycles of recurrence and of quiescence. The patient should be watched.

Dr. H. B. ANDERSON of Toronto asked where these cases originated.

Dr. HEMMETER said he thought they were all imported. In one healthy family in Baltimore there were three daughters affected. It was found that the nurse had been in Constantinople during the war. She had no symptoms but the stools were full of cysts. It was a rare infection and it was to be hoped that it would stay rare. One patient whom he had seen came from tropical regions.

Report of a Case of Encephalitis Lethargica.—Dr. WM. A. CAMPBELL of Colorado Springs reported this case. (See page 434.)

Dr. THOMAS F. REILLY of New York said that the study of these cases was very stimulating and interesting. There were three groups: (1) cases in which the diagnosis could be made at once; (2) those in which the disease was apt to be mistaken for some other, as typhoid fever, meningitis, or tuberculosis; (3) the very mild cases which passed without any attention at all, until perhaps some serious symptom happened. In one man seen with dyspnea and a temperature of 102° there was nothing found; the Widal was negative, all the tests were negative. The case was called typhoid fever. After a week or two there occurred a tremor of the diaphragm. The man got progressively worse, became somnolent, and died. The disease was diagnosed typhoid fever, but at autopsy it was found that the case was encephalitis lethargica. The tremor might be of value in doubtful cases but it was not present in all. In another case there was unusual vomiting, temperature of 102°, negative blood findings, and the case looked like tuberculous meningitis. There was partial Kernig. Sometimes this tremor or "shimmy" sign was present, sometimes not. One man said that if the case got well it was encephalitis, if it died it was tuberculous meningitis. Another case went insane and was transferred to Bellevue. There were psychoses, and the "shimmy sign" was present. There were double vision and other eye symptoms. At autopsy encephalitis was found. A year or two ago one would have called these patients insane. There was no doubt that many cases were picked up among the flotsam and jetsam of the city. These people had alcoholic history and were victims of exposure. The tremor recalled Parkinson's disease. It was not difficult to diagnose. The problem was for the neurologist. Many of these cases had no doubt been called neuritis. The patients came in complaining of a terrible pain, first on one side, then on the other. These were of thermic origin, with referred pain to the nerve branches. In one case a man complained that he went to sleep after luncheon every day and could not keep awake. The physician told him he had digestive symptoms. On questioning he complained of slight blurring in the eyes, stiffness in the back of the neck, and occasional pains in the legs or arms. On looking him over very carefully there was found a slight droop of the mouth on one side. He also said he had difficulty in urination. It was half an hour before he could start the stream. Such a patient would have been called neurasthenic two years ago, or he would have been given alkalies for indigestion. It was necessary to look very closely at these cases, and if this study cleared up some portion of that group of cases called neurasthenia, it would have been worth while. Seventy per cent. of the cases were associated with influenza and enlargement of Steno's duct was found in seventy per cent. The cases had been related to influenza as far as treatment was concerned. The "shimmy sign" was diagnostic. It was an involuntary clonic contraction of the muscles. Benzyl benzoate lessened the frequency of this contraction. Hexamethylenamine was used for internal treatment. One patient improved on large doses of iodine. There were no luetic symptoms.

Dr. A. E. ROUSSEL of Philadelphia said that a certain proportion of cases had not been recognized, but he could hardly agree with the last speaker that they were as common as he thought. He had seen nine cases in 1½ years. These were distinct cases of the so-called Parkinson type. One remained under treatment 6 months. He was seen by Drs. Anders, Stengel, and Dercum. Some of the other cases were seen in consultation. Dr. Roussel said he was rather sceptical about the introduction of new diseases. He remembered distinctly in 1889-90 he was assistant to Dr. Pepper and he saw a case of this type.. Epidemic cerebrospinal meningitis and anterior poliomyelitis were the only instances of comparatively well-defined new diseases. There was no doubt in his mind that this disease was the direct result of epidemic influenza. There is pretty clear clinical evidence of the disease. In some patients there are distinct somnolence, but in others the ptosis conveys an impression more apparent than real. There is hyperesthesia, the reflexes are increased and motor ocular symptoms were prominent; leucocytosis and orientation hallucinations were frequently present. The patient might have to be fed by rectal tube. In one instance, 14 months after discharge, there were slight evidences of difference on the two sides of the face, and tremor was still present, although otherwise the patient had gained. This could be called an influenza sequela. In one case a mother nursed two children with influenza. She did not have it herself, but had pain in her ears and consulted an aurist. The patient slept a good deal, but one could not state positively that this was a case. He did not think it so rare, nor yet so common, as some people supposed. The treatment was entirely symptomatic. Electricity was useful.

Dr. R. W. WILCOX of New York said that there were two or three points that should be emphasized. The condition under discussion was, in the vast majority of instances, associated with an infection. It need not be a specific one; various infections were followed by this disease. It was the experience of those who had seen a great deal of the condition that the most unpromising patients would recover, even after a considerable period of time. In one instance, resulting in a life insurance investigation, the speaker had been asked to decide whether a proprietary hypnotic had caused death. He decided that this cause could be excluded. In another instance, seen in consultation, he had directed a rather large hypodermic injection of caffeine salts to arouse the patient for feeding and for attending to the calls of nature, and this had led to a successful outcome.

Dr. JACOB DINER of New York said he was glad to hear the remarks of Dr. Roussel. The asthenia was often a sequel. There was probably a glandular disturbance, but this was not monoglandular. There was no such thing. It was a pluriglandular unbalance. There was evidently a marked disturbance of the endocrine system. One did not really know the name of this disease.

Dr. D. R. TUCKER of Richmond, Va., said that he had had considerable experience with encephalitis; he had reported eleven cases in the *Journal of the A. M. A.* in May, 1919, and had seen about nine cases since. He was interested in the 1899-90 epidemic in that the cases seemed to have followed influenza and that the Vienna workers had considered it an aftermath of influenza. Of his own cases three came to autopsy. None of these had meningitis, but there were cobweb adhesions over most of the lower part of the brain. The ventricles were dilated in all three cases, and in one case the patient had had eleven lumbar punctures. The pituitary body was swollen; the capsule was tight and there were capillary hemorrhages found in the gland in all three of these autopsies. He did not know what relation the pituitary had to the somnolence, but the pituitary was certainly greatly involved. Some of the patients had acidosis and most of them would wake to take food and medicine regularly. He advocated the use of urotropin, and, as the spinal fluid was always under pressure and the ventricles

were dilated, frequent lumbar puncture was advisable. He had tried a new treatment which had been used in England for violent cases of chorea. This consisted of withdrawing 50 c.c. of blood, centrifuging it until a clear serum was obtained, which was inactivated. From 18 to 25 c.c. of this serum was injected intraspinally, after an equal amount or more of fluid had been withdrawn. This was tried in two cases, and in each case the patient was greatly improved the next day. The method was repeated and still further improvement gotten. He suggested this as an interesting field for therapeutic investigation.

Dr. C. E. DE M. SAJOUS of Philadelphia said that the tendency to somnolence in influenza was accounted for by the newer pathogenesis of the disease he had previously submitted. Many years ago he had urged that the theory of respiration taught in text-books of physiology was erroneous and misleading, and was even yet responsible for the lack of progress in the successful treatment of our most deadly pulmonary diseases. The speaker in 1903 had pointed out, and it had been confirmed since, that the secretion of the adrenals furnished the substance which, in the alveoli, caused the hemoglobin to be converted into oxyhemoglobin, the substance through which all tissues, including the nerves, were oxygenized. As he had previously urged, in respect to influenza, the Pfeiffer bacillus found, in the pulmonary alveoli, when allowed by the defensive functions of the respiratory tract to reach these air vesicles, the very conditions (temperature, hemoglobin, and oxygen) needed in the laboratory to obtain cultures of this bacillus. These cultures causing, as stated, a necrotic alveolitis, the respiratory function was correspondingly reduced, a process entailing lowering of the oxygenizing properties of the blood, as well shown by the more or less marked cyanosis so often observed, and sufficient in some to cause the patient to become almost black. This explained, according to the speaker, the tendency to somnolence. In the lowered oxidizing activity of the body there was produced a condition of lowered metabolism so marked as to inhibit all the cellular functions, including those of the cerebrum, the somnolence in some cases reaching a condition of lethargy which had caused the condition to be mistaken for sleeping sickness or encephalitis lethargica in many instances.

Dr. SPRAGUE of Washington, D. C., said that he would believe anything of the influenza organism, and it was probable that it was the cause of the somnolence. Fifteen years ago he had found the Pfeiffer bacillus in pure culture in the spinal fluid of meningitis. Since this epidemic in the last two years they had seen many cases of encephalitis. There was some abnormal condition of the brain, and it was difficult to make the differential diagnosis between meningitis and encephalitis. One point to be noted was the occurrence of these diseases in pregnancy. He had had a patient referred last October, threatened with eclampsia. She was operated on for congenital absence of right kidney, tube and ovary. She was taken to Washington, and on arriving at the hospital could not be wakened up. The patient had endocarditis, and distinct vegetations were found. The woman died in hospital, but in that case no treatment could have made any difference. Fleeting paralyses occurred in that case. There was ptosis and anesthesia over one side of the body.

Dr. CAMPBELL, in closing, said that in the epidemic of 1889-90 he had seen cases of a lethargic, somnolent character which were then diagnosed as "nona." The conditions were identical with those now described under the name of lethargic encephalitis. Like cases had been described in the histories of all past epidemics. This would lead one to believe that there was some connection between encephalitis and influenza—that the germ causing influenza was a potent factor in causing encephalitis. Cultures from the nares had been carried to the eleventh generation, and when injected into a monkey caused typical encephalitis. Encephalitis had been noted following many acute infectious diseases. This would lead one to draw the deduction that encephalitis was not due to a specific infection from influenza—if there was one—but to a microorganism that was common to all the infectious diseases. He had recently been consultant in a case of encephalitis in a child of five years who commenced with an influenza attack followed by a suppurating mastoid (which was operated on), and this was followed by an encephalitis. While the discussion of symptoms might be important as helping one to make a proper diagnosis, he regretted that the discussion had not brought out more on the treatment of the malady.

A Case of Lymphosarcoma.—Dr. A. F. ROUSSEL of Philadelphia presented a case of lymphosarcoma which had infiltrated the lymph nodes and surrounding structures. The patient was sent to him as one of Hodgkin's disease. The woman was 32 years of age, married, and the glands had commenced to enlarge about two years ago. She had been treated with *x*-rays, but continued to grow worse, and at the time of admission to the Polyclinic Hospital, March 2, 1920, the visible glands in the neck and groins were the size of oranges, and an *x*-ray showed marked involvement of the bronchial glands. Sixteen injections in increasing doses of Coley's toxins had been given until the present time, with the remarkable result that not only were the glands no longer visible, but only one or two remaining small glands could be detected on palpation, and the last *x*-ray picture showed a nearly normal chest. It need hardly be mentioned that a microscopical diagnosis was made. Lymphosarcoma, he said, was a rare disease. It was a definite form of neoplasm arising in lymphoid tissue composed of lymphoblastic cells which did not remain confined to the involved nodes, but infiltrated the adjoining tissue. Distinct metastasis was rare, but all of the nodes might be more or less involved. The following regional types were to be noted: (1) Cervical, axillary, and inguinal; (2) thoracic, (*a*) thymic, (*b*) peribronchial; (3) abdominal (*a*) gastrointestinal, (*b*) intestinal, (*c*) retroperitoneal. In the thoracic type degeneration and softening were rare, but not in the abdominal type. Hodgkin's disease was an inflammatory condition rather than malignant, but it was not a degenerative process, as in syphilis or tuberculosis, but an active proliferation of all types of cells of the lymph glands, due to tuberculosis or other causes. The Coley fluid was the mixed toxins of erysipelas and *Baccillus prodigiosus*. The radium treatment should also be tried.

Dr. MORRIS of New York said that the reason of this remarkable result of the Coley toxins was that in some cases the patient was sensitized to the enzymes. The response to the toxins was an autolysis. Autolysis involves the embryonic cells. One could start out to sensitize the patient before using the toxin. That would open up a new era. One was beginning now to know something about medicine. It was so interesting that he would like to begin his professional life over again. He had seen the new growths disappear promptly in certain cases under the use of Coley serum, and he had come to the conclusion that the response was due to enzyme action.

Dr. L. H. TAYLOR of Washington, D. C., said he was interested in this treatment. He had had one or two cures, but in six cases there was no appreciable result. In one instance he had such a severe reaction to the Coley serum that it was impossible to persuade the patient to go on with the treatment. The reaction was worse when the injection was near the growth. The result was due to necrosis of the sarcoma cells. The growth reacted beneath the skin and discharged necrotic material. In one case the patient had a growth in the gums. He recovered after 12 injections, after a period of intense pain and suffering. In another case there was a spindle celled sarcoma which involved the tendon of Achilles. The man refused to submit to amputation, nevertheless the patient was cured. Both patients had lived ten years.

Dr. H. ANDERSON of Toronto said he knew of one case of a young woman of 23, with an immense mass on the side of the neck. She was referred to Dr. Coley. The mass continued to grow. One day on board ship, going to Europe, she fell on deck and struck the mass. After that it commenced to disappear, and in one year had disappeared.

Dr. ROUSSEL said that he refrained from giving injections locally in that case. The reaction was less when the injection was made at a distance from the site of the tumor.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

TEXAS STATE BOARD OF MEDICAL EXAMINERS.

November, 1919.

(*Continued from page* 546)

BACTERIOLOGY.

1. Name three common pyogenic bacteria. Where are they found in health? Where in disease? Give usual method of staining.
2. Describe the diphtheria bacillus. How would you obtain a specimen for examination, and how would you determine when to release a patient from quarantine?
3. Tell in detail the technique employed in detecting malarial organisms in the blood, and how to distinguish between the quartan and estivoautumnal parasites.
4. What is Ehrlich's side-chain theory of immunity?
5. What is meant by phagocytosis? In what way is it a protective agency to the body?
6. What conditions are essential to the life of bacteria?
7. What are sterilization, antiseptics, disinfectants and germicides?
8. What is tuberculin? Describe the general reaction following the use of tuberculin.
9. What is the specific test for syphilis? Upon what principle does the test depend?

PHYSICAL DIAGNOSIS.

1. Differentiate mitral regurgitation from mitral stenosis.
2. Differentiate emphysema from pneumothorax.
3. Differentiate renal calculus from lumbago.
4. Describe the clinical manifestations of acute nephritis.
5. How would you distinguish amyloid disease of the liver from cirrhosis of that organ?
6. What are the symptoms and physical signs of acute dilatation of the heart?
7. For what conditions might cerebral hemorrhage be mistaken?
8. Give indications of tumor of spinal cord.
9. How would you distinguish paralysis of the musculospiral nerve from the neuritis due to lead poisoning?
10. What are the clinical manifestations of rachitis?

OBSTETRICS.

1. Give maternal locations of fetal heart beats in twin pregnancy at the ninth month.
2. Differentiate a knee from an elbow presentation, and describe procedure of delivery in each case.
3. Describe the mechanism of the left occipito-posterior position.
4. Name all the conditions which retard or obstruct labor.
5. How would you suspect placenta prævia after the fifth month of pregnancy? Give management of such a case.
6. Give detailed description of the care of the child immediately after birth.
7. What changes occur in the uterus during pregnancy? What after birth?
8. What is meant by dystocia, and how would you determine the nature and degree of dystocia? Name all its different causes.
9. What measures would you adopt to prevent an anticipated puerperal eclampsia?
10. Describe delivery of a hydrocephalic fetus when uterine inertia exists to such an extent that parturifacient drugs will not act.

ANSWERS.

BACTERIOLOGY.

1. *Three common pyogenic bacteria: Staphylococcus pyogenes aureus, Staphylococcus pyogenes albus*, and *Streptococcus pyogenes.*

In *health* they may be found on the surfaces of the body (both cutaneous and mucous), skin, hairs, sweat glands, nose, mouth, gastrointestinal tract, and genitourinary tract.

In *disease* they may be found in abscesses, boils, phlegmons, and suppurative inflammations; in phlebitis and lymphangitis; in septicemia, pyemia, and erysipelas; in pneumonia, bronchitis, endocarditis, arthritis, and osteomyelitis.

General method of staining bacteria: "Nearly all the known bacteria are readily stained by the watery solutions of any of the basic anilin dyes. The film on the slide or cover-glass, properly prepared, is covered by a few drops of the stain, or the cover glass, *film-side down*, is floated in a watch-glass full of the staining solution; at the end of from one-half to two or three minutes the staining fluid is poured off, the slide or cover-glass washed rapidly in water and then allowed to *air-dry;* after which, in the case of cover-glass preparations, they are inverted upon a drop of Canada balsam on a slide and examined with the oil-immersion lens; or, when slides have been prepared, after washing and drying a drop of cedar oil is put over the preparation, and the same is examined with the oil immersion objective, without the use of a cover-glass." —(Archinard's *Bacteriology.*)

2. The *characteristics of the bacillus of diphtheria:* The bacilli are from 2 to 6 mikrons in length and from 0.2 to 1.0 mikron in breadth; are slightly curved, and often have clubbed and rounded ends; occur either singly or in pairs, or in irregular groups, but do not form chains; they have no flagella, are nonmotile, and aërobic; they are noted for their pleomorphism; they do not stain uniformly, but stain well by Gram's method and very beautifully with Loeffler's alkaline methylene blue.

A sterile swab is rubbed over any visible membrane on the tonsils or throat, and is then immediately passed over the surface of the serum in a culture tube. The tube of culture, thus inoculated, is placed in an incubator at 37° C. for about twelve hours, when it is ready for examination. A sterile platinum wire is inserted into the culture tube, and a number of colonies of a whitish color are removed by it and placed on a clean cover slip and smeared over its surface. The smear is allowed to dry, is passed two or three times through a flame to fix the bacteria, and is then covered for about five or six minutes with a Loeffler's methylene-blue solution. The cover slip is then rinsed in clean water, dried, and mounted. The bacilli of diphtheria appear as short, thick rods with rounded ends; irregular forms are characteristic of this bacillus, and the staining will appear pronounced in some parts of the bacilli and deficient in other parts.

A patient may be released from quarantine when repeated examinations of the discharges from his nose and mouth are negative.

3. *In examining for malaria:* "Prepare some perfectly clean and very thin cover slips, and remove all traces of grease. Cleanse the skin of the finger-tip or ear with soap and water, and then with alcohol and ether. Make a *small prick* in the skin. Wipe away the first drop of blood, leaving a perfectly dry surface, so that subsequent drops will not run. Squeeze out a tiny drop about the size of a large pin's head. Touch the apex of this drop with the center of a cover glass, and immediately drop it, face downward, on a perfectly clean slide. Make several such preparations, and reject all those in which rouleaux are present. It is absolutely essential that the red corpuscles should lie flat. Examine with a 1/12 immersion lens and rather feeble illumination. Look in the red corpuscles for the presence of small black specks, often rod-like and showing slow movements of translation. These are surrounded by clear areas. One may also see in the center of some of the red cells clear ameboid areas which show no pigment. Rosette forms may also be visible. These forms of the parasite are always present in cases of malaria which have not had quinine. Other varieties are only met with in some chronic cases. Of these there are two chief forms: (1) The crescentic, (2) the flagellated. These are easily recognized. The crescentic bodies are highly refractile, rather longer than a red blood corpuscle, and about 2μ in diameter. Particles of pigment may be recognized in the parasite and also in some of the ordinary leucocytes."—(Hutchinson and Rainy.)

DIFFERENCES BETWEEN THE PARASITES.

QUARTAN.	TERTIAN.	ÆSTIVO-AUTUMNAL.
Cycle three days.	Forty-eight hours.	Forty-eight hours.
Ameboid motion sluggish.	Rapid.	Brisk.
Red cell slowly decolorized.	Rapidly.	Cell becomes darker, bronze-like.
Little change in size of red cell.	Much swollen.	Cells small and shriveled.
Parasite sharply outlined.	Indefinite.	Faint.
Pigment granules coarse and few, and in slight motion.	Fine and numerous; in active motion.	Granules fine, not often in motion.
Spores six to twelve, large and pear-shaped.	Fifteen to twenty, small, round.	Six to twelve small spheres present.

—(From McConnell's *Pathology.*)

4. *Ehrlich's side chain theory of immunity:* "This receives its name from its analogy to the benzole ring in chemistry with the accompanying lateral chains. For convenience terms are used that can be applied to formed bodies, although they cannot be demonstrated as such in body juices. In this theory it is claimed that immunity depends upon the presence or absence of 'receptors,' the equivalent of the chemical lateral chains. The normal or fixed receptor is that body attached to the cell by means of which the cell is acted upon by various substances, nutritive or otherwise. Each receptor is supposed to be so formed as to unite with a certain body of a definite character. When the action of the bacteria upon the tissue cells is considered, it is supposed that the poisonous products consist of two portions, the 'haptophorous' and the 'toxophorous' groups. The combination is thought to take place as follows: The haptophoric group unites with a certain definite receptor, and by so doing interferes with the normal function of the cell. At the same time the toxophoric group is able then to act directly upon the cell. If this group is very powerful the cell is destroyed, and if a sufficient number are involved the individual may die. When such a union occurs the receptors are of no further use. It has been found in such cases that in order to get back to the normal the cell will be so stimulated that new receptors similar to the ones destroyed will be formed. As a rule, a great excess of receptors will result, and many of these will be cast forth into the circulation, becoming free receptors. These cast-off receptors are what constitute an antitoxin, and on coming in contact with the toxin molecule, unite with the haptophorous portion and consequently render it harmless. It being attached to a free receptor, it is no longer able to combine with a fixed receptor. In bacteriolysis and hemolysis, or cytolysis in general, conditions in which the destruction of actual cells is concerned, the destruction is brought about in a more complicated manner. Two other bodies than the cells are involved. One of these, known as the complement, is normally present in all serum. It is destroyed by a temperature of 55° C. for one-half hour, and is termed, therefore, thermolabile. The other, the immune-body, or amboceptor, occurs in serum only as the result of the injection into the individual of the definite antigen. In other words, the amboceptor is specific in that it can combine only with that substance which gave rise to its formation. As it can resist heat up to 80° C., it is termed thermostabile. In order that the cell be destroyed the complement unites with the specific amboceptor, which in turn joins with the fixed receptor, and the destructive action then occurs. In active acquired immunity against foreign cells the invaded animal forms large amounts of amboceptor, which, being free within the blood, unite with and destroy the invading cells. If the supply is sufficient, the individual will recover. In passive acquired immunity large numbers of amboceptors in the serum from the immunized animal are directly introduced into the patient, and in this way effect a cure."—(McConnell's *Manual of Pathology.*)

5. *Phagocytosis:* "There are certain cells in the body that have the power of ameboid movement, by means of which they are able to surround and take up bacteria and destroy them. These cells are known as phagocytes. Metchnikoff believes that immunity is the result of the positive and negative chemotaxis (power of attraction) existing between the phagocytic cells and the microorganisms. He divides such cells into two classes: (1) *Microphages,* represented by polymorphonuclear leucocytes; and (2) *Macrophages,* large mononuclear leucocytes, endothelial cells lining serous membranes, and fixed mononuclear cells of the spleen follicles and lymph sinuses. The most active are the microphages, as they have the power of independent motion. When the bacteria gain entrance into the body, the phagocytes are attracted, and they attempt to ingest and destroy the invaders. If the immunity of the animal is marked, many of the organisms will be bound within the cells; if the immunity is slight, few cells will contain bacteria. At one time it was claimed that phagocytes could take up only dead bacteria, but it has been demonstrated that the leucocytes can take up living organisms. As a rule the bacteria are ultimately destroyed, but on the other hand, the phagocyte may be the one to perish, and in this way permit a wide distribution of the invaders. Experiments have shown that the bacteria must be acted upon by a substance in the blood known as an *opsonin,* before the phagocyte is able to digest them."—(McConnell's *Manual of Pathology.*)

6. *Conditions essential to the life of bacteria:* (1) Suitable *temperature,* which varies with different bacteria; the optimum temperature of most of the pathogenic bacteria is near that of the human body. (2) Absence of *sunlight* or bright light. (2) Slight *moisture.* (4) The presence of *oxygen* for aerobes, and the absence of *oxygen* for anaerobes. (5) Suitable *food,* organic nitrogenous matter being generally desirable. (6) The food medium should be neutral or slightly acid in *reaction.* Individual bacteria may have specific needs in many of these (and other) requirements.

7. *Sterilization* is the process of freeing a substance from the live bacteria that may be on it or in it.

Antiseptics are agents which prevent or restrain putrefaction.

Disinfectants are agents which restrain infectious diseases by destroying or removing their specific poisons.

Germicides are agents which destroy bacteria and their spores.

8. *Tuberculin* is a glycerin extract of cultures of the bacillus of tuberculosis. It is used as a means of diagnosis of tuberculosis.

Von Pirquet's test is a tuberculin test for the presence of tuberculosis. Two small drops of old tuberculin are placed on the skin of the front of the forearm about two inches apart, and the skin is slightly scarified, first at a point midway between them, and then through each of the drops. In about ten minutes the excess of tuberculin is gently wiped away with cotton. No bandage is necessary. A positive reaction is shown by the appearance in twenty-four to forty-eight hours of a papule with red areola, which contrasts markedly with the small red spot left by the control scarification.

9. The *specific test for syphilis* is called the Wassermann reaction. "The reaction depends upon the fact that when an antigen, *i.e.* a substance capable of stimulating the formation of antibodies in animals or man, is mixed with its inactivated antiserum, in the presence of complement, the complement is firmly fixed by the combined immune body and antigen in such a way that it can no longer be found free in the mixture. If such a mixture is allowed to stand at a suitable temperature for an hour or more, and to it is then added an emulsion of red blood cells together with a suitable quantity of inactivated hemolytic serum, no hemolysis will take place, since there is no free complement available to complete the hemolytic system. If, on the other hand, the original mixture contains no antibody for the antigen used, the complement present is not fixed and is available for the activation of the hemolytic serum later added. The reaction thus depends, in principle, intimately upon the fact that neither

antigen alone, nor amboceptor (antibody) alone, can fix complement, but that this fixation is carried out only by the combination of antigen plus amboceptor. Any specific amboceptor can be determined by this method, provided the homologous or stimulating antigen is used; and *vice versa*, by the use of a known antibody a suspected antigen may be determined."—(Hiss and Zinsser's *Bacteriology.*)

PHYSICAL DIAGNOSIS.

1. In *mitral regurgitation*, there is a systolic murmur, heard loudest over the apex, and transmitted round to the left axilla and under the left scapula; the murmur is soft and blowing.

In *mitral stenosis*, there is a presystolic murmur, heard loudest over the apex, and not transmitted; the murmur is generally low-pitched, and rough.

2.

EMPHYSEMA.	PNEUMOTHORAX.
1. Frequently sequel of chronic bronchitis; disease bilateral.	1. Sequel of tuberculosis; empyema may result from traumatism; disease unilateral, as a rule.
2. Emphysematous chest.	2. Phthisical chest or normal.
3. Diminished vocal fremitus.	3. If due to phthisis, vocal fremitus is increased.
4. Succussion produces no abnormal sound.	4. Succussion produces a splashing sound; metallic tinkling may be heard.
5. Heart seldom displaced; upper border of heart dullness depressed.	5. Heart generally displaced.

(From *Pocket Cyclopedia of Medicine and Surgery.*)

3. *Renal calculus:* Symptoms consist of pain in the loins, markedly increased by exercise, especially on jolting. The pain may be referred to the thigh, groin or testicle. The colic is associated with hematuria, and often pyuria exists with frequency of micturition. The kidney may be enlarged, and tender on pressure. A large stone may exist without any symptom whatever. The most typical symptom consists in a sudden attack of excruciating and paroxysmal pain shooting down the loin to the bladder and testis. The attack is accompanied by vomiting, faintness, and collapse. Frequent efforts to pass urine are made, but only a scanty amount of blood-stained urine is passed. The pain ceases suddenly when the calculus slips back into the pelvis or reaches the bladder.—(*Aids to Surgery.*)

The *x*-ray may show the calculus.

In *Lumbago* there are no urinary symptoms, and the *x*-ray examination will be negative.

4. *Acute nephritis:* "In mild cases, slowly developing dropsy with anemia, shortness of breath or dyspnea, and weakness are the only symptoms, the diagnosis being confirmed by the results of urinary examination. Usually, however, it begins suddenly with nausea, violent and persistent vomiting, fever, and dull pain over the kidneys, following the course of the ureters. There is a frequent desire to urinate, and diarrhea, harsh and dry skin, and a quick, tense, and full pulse are present. Dropsy soon appears, beginning first in the eyelids and face, but later becoming generalized. Anemia and weakness are marked, particularly in post-scarlatinal cases. Uremic symptoms may develop at any time during the attack. The affection lasts from one to four weeks. The *urine* is of high specific gravity, 1025 to 1030, scanty, smoky (like beef washings) in color, due to the presence of blood. Albumin is present in large quantities, and the microscope reveals hyaline, blood, granular, and epithelial casts of the uriniferous tubules, blood corpuscles, uric acid, urates, oxalate crystals, and epithelium. The total amount of urea eliminated during the twenty-four hours is lessened from one-fourth to one-half. The amount of phosphates and chlorides is also lessened."—(Hughes' *Practice of Medicine.*)

5. The diagnosis of *hypertrophic cirrhosis of the liver* is based on: "The chronic enlargement of the liver and spleen; the persistent jaundice; a tendency to hemorrhages; and the absence of ascites. The affection is to be differentiated especially from amyloid disease, sometimes from abscess or carcinoma of the liver, and echinococcus cyst.

Amyloid disease follows a history of suppuration, tuberculosis, or syphilis; the skin is waxy, seldom jaundiced. The liver is hard, and other organs are affected.—(French's *Practice of Medicine.*)

6. CARDIAC DILATATION. *Symptoms:* "The manifestations are referable to the enfeebled circulation and include feeble pulse, headache aggravated by the upright position, attacks of syncope, cough, dyspnea, jaundice, dyspepsia, constipation, scanty, often albuminous urine, mental dullness, vertigo, often relieved by a copious epistaxis, and finally dropsy beginning in the lower extremities. The condition terminates in death by exhaustion. Treatment may serve to temporarily relieve any of the symptoms just mentioned."

Physical signs: "*Inspection* detects enlargement and distention of the superficial veins and an indistinct, often wavy and diffused, cardiac impulse. If tricuspid regurgitation is present, jugular pulsation will be observed. *Palpation* confirms inspection; the impulse is feeble, irregular, and heaving. *Percussion* serves to determine extension of the area of cardiac dullness transversely and especially toward the right side. *Auscultation* in the presence of valvular lesions reveals characteristic murmurs. If there are no valvular lesions the cardiac sounds are weaker than normal and the first sound is sharper in quality than usual."—(Hughes' *Practice of Medicine.*)

7. *Cerebral hemorrhage might be mistaken* for: Alcoholism, opium poisoning, uremia, cerebral embolism, or thrombosis, syncope, epilepsy.

8. *Tumors of the spinal cord* "develop in several situations, and the symptoms are thereby somewhat modified. (*a*) *Outside the spinal dura.* Lipoma and sarcoma are here most often seen, and the symptoms of cord pressure, such as loss of power and sensation, are preceded by those of spinal irritation, *e.g.* neuralgic pain, increased on movement, and are often limited for some time to one side. Multiple neuro-fibromata of the nerve roots are by no means uncommon. (*b*) They may grow *from the inner aspect of the dura mater*, and thus produce symptoms of cord pressure and meningeal irritation concurrently. Sarcoma, endothelioma, fibroma, and gumma, are the commonest forms of neoplasm in this situation. (*c*) *From the spinal cord* itself, myxoma, psammoma, and sarcoma may originate. The symptoms are those of paraplegia combined with some localized and referred pain or tenderness, and either bilateral from the start, or sometimes of the crossed type, anesthesia being marked on one side of the body, and paralysis and hyperesthesia on the other —*i.e.* on the side of the tumor."—Rose and Carless' *Manual of Surgery.*)

9. *Musculospiral paralysis:* "The symptoms of this paralysis are 'wrist-drop,' due to an inability to extend the wrist or fingers. The first and second phalanges can be extended somewhat by the interossei and lumbricales, but the last phalanges cannot be extended at all. The first finger is least affected. The fingers can be only slightly abducted, supination is generally lessened or lost; if the lesion is high up, the triceps is involved and the power of extending the forearm weakened. There may be atrophy of the muscles and degeneration reaction. A swelling over the tendons of the wrist-joint may occur. Some numbness and tingling exist, and occasionally there is anesthesia in the distribution of the radial nerve on the hand. The disease lasts but a few weeks if due to compression; for months if due to neuritis, lead poisoning, or severe injury of the nerve. Eventually recovery takes place, as a rule.

"When the disease is due to *lead poisoning* there are some peculiarities in its course. Thus the supinator longus usually escapes; the palsy begins gradually and usually involves both arms; it may extend to the upper arm. Partial degeneration reactions are present. There is rarely any anesthesia and but little pain. Often there is a lead line on the gum and a history of constipation and colic."—(Dana's *Textbook of Nervous Diseases.*)

10. RACHITIS: "The head is elongated from back to front, the forehead is square and overhanging, the fontanelles are slow in closing, and the veins in the

skin are distended. The flat bones are usually much thickened, and frequently 'bossed' by irregular masses of calcified material. Often, however, the occipital bone and certain parts of the parietal bones are *thinned.* Though the skull as a whole is enlarged, the puny face makes the enlargement more noticeable by comparison; measurements show the enlargement to be more apparent than real. *The ribs* often show characteristic 'beading' at the junction of the costal cartilages (*rhachitic rosary*). Pressure of the external air on the softened anterior ends of the ribs produces the 'rickety chest,' characterized by a shallow vertical depression on each side of the sternum. *'Pigeon breast'* is due to impeded inspiration, as is 'Harrison's groove,' a transverse depression running from the xiphoid cartilage toward the axilla. *The lower limbs* are bowed, or sickle-shaped, and show well-marked epiphyseal enlargements, especially at the lower end of the *tibia. The upper limbs* also show the most marked changes at the lower ends of the ulna and radius, but the humerus and clavicle may also be affected. *The pelvis* is often much deformed. *The spine* is bowed forward from muscular weakness. There may be lateral curvature. The deformities, dependent partly on excessive deposits of calcareous material, are largely due to the yielding of the softened bone to mechanical causes; hence the necessity of rickety subjects avoiding any undue or avoidable strain, such as too early walking. The most prominent *general symptoms* are three: profuse sweating of the head at night, throwing off the bedclothes even in cold weather, and crying on being moved or handled. The mind is often backward; the body is stunted and may be emaciated, but the abdomen is prominent from flatulent distension, and from the enlargement of the liver and spleen. The bowels are sometimes costive, sometimes loose, and the stools are usually pasty, or green like boiled spinach, and very fetid."—(Wheeler and Jack's *Handbook of Medicine.*)

OBSTETRICS.

1. Normally, the position of the fetal heart-sounds is as follows: In L. O. A. and R. O. A., they are best heard one inch below and one inch to the left or right (respectively) of the umbilicus; in L. O. P. and R. O. P., one inch below and well over in the left (or right) flank.

In twin pregnancy there may be two heart-sounds, of different rates, heard at different points over the abdomen, possibly on opposite sides, and separated by a space over which they are heard indistinctly or not at all. Sometimes only one can be heard.

2. In the *knee* presentation, the flat patella may be felt; there are also two tuberosities with an intervening depression; abdominal palpation will show that the fetus is in a more or less vertical position.

In the *elbow* presentation, the sharp point of the olecranon will be felt, with a depression on one side; there are also two lateral prominences; abdominal palpation will show that the fetus is in a transverse position.

In the *knee* presentation, delivery is effected as in cases of breech presentation. "Before labor external version may be attempted. It will not always be found practicable, and after the fetal body has been turned there is a disposition on the part of the fetus to resume its original position. The application of two long cylindrical compresses to the sides of the uterus, and a firm abdominal binder, may prevent a return of the breech presentation. When labor has begun, inaction should be the physician's policy until the fetal body is born to the umbilicus, unless maternal or fetal life is threatened or an indication for rapid delivery arises. As soon as the trunk appears the patient should be placed in the lithotomy position across the bed, and delivery of the shoulders and head should be effected by pressing upon the fundus with one hand, the other hand being inserted in the vagina to favor anterior rotation of the shoulder, anterior rotation of the occiput, and to direct the passage of the head through the vagina."—(Hirst's *Obstetrics.*)

In the *elbow* presentation, version should be performed, and the delivery effected for the vertex or breech presentation which results.

3. *The normal course of delivery in occipito-posterior positions* is the same as in occipito-anterior positions except that the head must rotate to the front through three-eighths of a circle; of course this takes longer and is more tedious.

In abnormal cases the management is as follows:

"(*a*) *When diagnosed while the head is at the brim.* (1) Leave it alone. The occiput will probably rotate to the front all right if it is given plenty of time. (2) If flexion appears to be deficient, try to increase it by pushing up the sinciput with the fingers in the vagina during a pain, at the same time pressing down upon the fundus with the other hand. (3) The head may be rotated by passing the hand into the vagina and grasping it between the fingers and thumb. At the same time the shoulders must be rotated by abdominal palpation, or else the head will at once go back to its original position. This maneuver generally requires an anesthetic.

"(*b*) *When diagnosed after the head has entered the pelvis.* (1) Leave it alone. After exercising the patience of all concerned, it will probably rotate spontaneously. Only about one case out of twenty fails to do so. (2) An attempt may be made to increase flexion as before. (3) Manual rotation may be attempted as before, but the head must first be flexed and gently pushed back out of the pelvis. (4) If the pains are weak, forceps should be applied well back on the head, so that when traction is applied, flexion will be promoted. The head should then be pulled well down on to the pelvic floor. If it begins to rotate, take off the forceps and leave the rotation to nature, merely keeping the head on the pelvic floor by pressure on the fundus. After rotation the forceps may, if necessary, be reapplied and delivery completed.

"(*c*) When the occiput has definitely rotated into the hollow of the sacrum, and the case has become a persistent occipitoposterior, forceps should be applied and the head delivered with the occiput posterior. The perineum should be guarded as much as possible, and any tears stitched up at once. In extreme cases craniotomy and pubiotomy may require to be considered."—(Johnstone's *Textbook of Midwifery.*)

4. *Conditions which retard or obstruct labor:* Uterine inertia; rigid cervix; breech presentations; twins; contracted pelvis; pelvic tumors; transverse presentations; hydrocephalus; faulty attitude or position or presentation of the fetus; rigidity or atresia of the vagina and vulva.

5. PLACENTA PRÆVIA: There is generally a sudden hemorrhage, accompanied by syncope, vertigo, restlessness, and feeble pulse. On examination placental tissue will be found over the internal os.

Treatment before term: Rest in bed, with or without a *tampon,* will arrest hemorrhage for the time; the sinuses are closed by thrombi, and the case may go on to term or another hemorrhage. The patient should be allowed cold drinks; opium may be used where pain is present. If the hemorrhage is great it is safer to induce labor at once than to wait. Occasionally no hemorrhage occurs during pregnancy, not even in labor.

Treatment at term: (1) Introduce one or two fingers within the os (the hand being in the vagina) and dissect the placenta from the uterine wall for about three inches from the os uteri in all directions, pushing it to one side if necessary. (2) Rupture the membranes, and if there is an unfavorable presentation, turn the child and make the breech engage in the os; or, if the head presents, the forceps may be used, if speedy delivery is necessary. Stop the hemorrhage by a tampon; this must be tight and thorough. *Accouchment forcé* is indicated; this consists of dilatation of cervix, version and immediate extraction of the child.

6. *Care of infant:* "After the cord has been ligated and cut, the eyes should be cleansed with a saturated solution of boric acid, after which, if there is any vaginal discharge from the mother, 1 or 2 drops of a 1 per cent. solution of silver nitrate should be instilled in each eye. The mouth should also be gently cleansed, for which may be used a soft cloth and boiled water. The vernix caseosa should be removed by means of some oily substance. The baby should be bathed in water at 100° F., carefully dried, and the cord dusted with some antiseptic powder. Sponging should be practised for ten days, after which a full tub bath at 98° F. should be given daily for 6 months. The temperature may then be reduced to 95° F., and at the end of a year to

90° F. The binder and clothing should be woolen. If the infant's extremities are blue or cold, external heat should be applied. The diapers should be made of flannel, and dusting-powders should be used to prevent chafing. An infant may be taken out-of-doors in summer when one week old, and in winter on pleasant days at 3 months of age. The new-born infant should sleep about 22 hours out of a possible 24, gradually diminishing this until at 2 years the child should sleep at least 12 hours of the day, and at 3 years not less than 11. The sleeping-room should be well ventilated.—(*Pocket Cyclopedia.*)

7. *Changes in the uterus during pregnancy:* "Before impregnation the length of the uterine cavity is about 2½ inches; at term it is increased to 12 inches, while its breadth is 9 inches and its depth 8 inches. The capacity changes from little more than 1 cubic inch to more than 400 cubic inch, and its weight increases from about 1 ounce to the neighborhood of 2 pounds. At first the uterus is changed from a flattened, pyriform body to a spherical or fig-shape, and after the fourth month to an ovoid. During the early months the uterus descends into the pelvic cavity. After the third month it rises steadily until the fundus reaches the epigastrium in the ninth month, but before term the fundus sinks again. During the first three months the womb exhibits a sharp anteflexion. The cervix is softened and somewhat hypertrophied during the first four months, but its canal is undilated until the first stage of labor begins. Throughout the whole duration of pregnancy the canal remains unaltered in length. The mucous glands of the cervix secrete a peculiarly tough mucus (mucous plug), which stops up the cervix like a cork during pregnancy.—(From Hirst's *Textbook of Obstetrics.*)

After labor, a process of physiological atrophy goes on in the uterus, and the tissues return almost to the condition in which they were before pregnancy. This process is called involution.

8. Dystocia, or pathological labor, is the term applied to labor which, without artificial assistance, would be difficult or impossible, or would be attended with danger to mother or child. Every case of labor is a mechanical problem in which the three main factors are the expelling force, the fetus which is to be expelled and the resistance of the parturient canal. So long as these three main factors are properly correlated, all goes well; but if their harmonious action be impaired, the normal mechanism of labor may be disturbed, and dystocia may be the result. In the management of a case of dystocia the recognition of the disturbing cause forms the basis of rational treatment.

Varieties of dystocia: These may be classified, according to causation, as follows:

(1) *Anomalies of the expellent forces:* (*a*) Excess—precipitate labor; (*b*) deficiency—delayed or protracted labor and inertia uteri; (*c*) spasm and irregularity—rigid os and cervix, and tetanus uteri.

(2) *Anomalies of the passages:* Pelvic deformities; uterus, developmental anomalies of, atresia of cervix, rigidity of cervix, impaction of cervix, malposition, sacculation, and new growths; stenosis and rigidty of vulva and vagina; hematoma or edema of the vulva; labial abscesses and cysts; conditions of intestines or bladder; tumors and swellings of various tissues.

(3) *Anomalies of the fetus:* Malposition of the head; occipito-posterior cases; malpresentations—face, brow, pelvic, and transverse; prolapse of limbs; anomalies of fetal development—shortness of cord, unduly ossified skull, large size of fetus, death of fetus, and enlargement of head or body by disease; plural births, and monstrosities (modified from Jewett's *Practice of Obstetrics*).

9. "*The prophylactic treatment of puerperal eclampsia* consists in frequent and regular examination of the urine. After the first appearance of albumin, daily quantitative examination of the urine should be made. The diet should be milk; the bowels should be kept freely open by means of calomel and salines; the skin should be kept active by hot baths, followed by vigorous rubbing. Diuretics, such as Basham's mixture, digitalis, and caffeine, should be administered. During pregnancy, if the percentage of albumin increases in spite of the treatment, abortion or induction of labor is indicated."—(*Pocket Cyclopedia.*)

10. In the case of *hydrocephalus,* "the ideal treatment is to tap the dropsical head with a trocar, draw off the fluid, dilate the cervix if necessary with a water-bag, and then perform podalic version when it is fully dilated. In this way there is a slender chance of a living child being delivered which, after giving a great deal of trouble to its mother and nurse, will probably die within a year, but has a remote chance of growing up into a deformed imbecile. The usual treatment (as a trocar and cannula are not generally carried in the obstetric bag) is to perforate and deliver with the cranioclast or cephalotribe as soon as the diagnosis is made. This is safer for the mother, as there is a slight risk of rupturing the uterus in introducing the hand for turning. The after-coming hydrocephalic head has been known to burst under traction used for delivery. The proper treatment is to perforate as soon as it is clear that the head is so large that it cannot be delivered quickly. The death of a hydrocephalic fetus is not a misfortune."—(Herman's *Difficult Labor.*)

BULLETIN OF APPROACHING EXAMINATIONS.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular state.

Lichens and Lichenification.—Dind discusses in a serial article numerous dermatoses which have hitherto been classed as lichen or lichenoid eruptions. He pays special attention to the socalled neurodermitis, prurigo of Darier and prurigo of Besnier, conditions which to a certain extent have superseded the old and conventional lichens of authors. Thus the old lichen of Vidal is now claimed as a special form of neurodermitis and lichen ruber in its clinical varieties belongs under the same general head.—*Annales de dermatologie, etc.*

Miscellany.

The Sexual Differences of the Atlas.—In the *Progrés Médical* for June 19, 1920, xlviii, 25, there appears a communication from Dubreuil-Chambardel, chief of the anatomical department of the Medical School of Tours, who claims that he drew attention to sexual differences in the atlas as far back as 1907 before the *Société d'Anthropologie* of Paris. The article appears on page 309 of the transactions for that year and goes into the subject minutely, giving many measurements. A discussion followed in which Baudouin, who has recently written on the subject, participated. It was remarked that the discovery was of archeological value as well as forensic. But in his recently published article on sexual differences of the atlas Baudouin for some unknown reason suppressed the author's name. He has evolved the conception of the glenoid index, which he based on a few cases. But Dubreuil-Chambardel has studied the glenoid cavity in hundreds of skeletons and, like his predecessor Lenoble, found it subject to extreme variation. He therefore preferred as more constant the totality of the lateral masses of the atlas. Baudouin appends his reply to the above letter of his colleague, disclaiming any intention of reviewing the entire history of the atlas as an organ of sex differentiation. He sought only to make an announcement concerning the glenoid index. His colleague seems to have no priority claim for the latter nor have his remarks invalidated the claims made for the index.

London Fellowship of Medicine.—The Fellowship of Medicine was founded in July, 1918, at a meeting convened by Lord Eustace Percy, with a view to establishing a body which might unite the British profession with their overseas brethren in closer bonds of sympathy. Sir William Osler acted as president to the time of his death. During the last twelve months the organization of the Fellowship has been quietly proceeding, and the many opportunities for post-graduate study offered by London are being coordinated and augmented. To those who subscribe to the monthly ticket of the Fellowship practically every door in medical London is open, and small additional fees will admit him to special lectures if they are not already free.

American medical men who are considering the desirability of study in Europe are invited to apply for a post-free copy of the weekly Bulletin of the Fellowship, which provides a daily program of the work in the wards and out-patients' departments, together with a syllabus of each special course and list of all current lectures. The Fellowship also collates information of post-graduate work in the United Kingdom and in Paris, where a permanent branch is in course of being established. Correspondents should state the subjects they are interested in, and announcements of forthcoming arrangements will be forwarded from time to time. The offices of the Fellowship of Medicine and Post-Graduate Medical Association are at present in the House of the Royal Society of Medicine (by courtesy of the Royal Society of Medicine), No. 1 Wimpole Street, London, W.1., England.

Therapeutic Hints.

Burns.—McGeary gives the following formula for the preparation of paraffin dressings used as the routine treatment of burns at the Minneapolis City Hospital:

1. Resorcinol	10
2. Olei Eucalyptii	20
3. Olei Olivae	50
4. Petrolatum	250
5. Paraffin	670

Melt 4 and 5 together.

Dissolve 1 in alcohol and add to 4 and 5 while latter is hot, to drive off the alcohol. When cool, add 2 and 3.

The dressing is applied daily until healing is complete. The area is first washed with Dakin's solution. —*Minnesota Medicine.*

Dogwood for Labor Pains.—An Indian observer (Rai Saheb Thakur Ram Dhari Sinha) states that Jamaica dog wood (*piscidia erythnena*) appears to possess the good qualities of opium without the bad. In one-half dram doses it is an elegant palliative in the pains of labor.—*Indian Medical Record.*

Infectious Diarrhea.—Edward A. Morgan gives the following indications for the treatment of infectious diarrhea: (1) neutralization of specific toxins by injection of a specific antitoxin if this is available; (2) correction of dehydration by saline or glucose injections; (3) prevention of formation of toxic products of protein putrefaction by administration of a food rich in carbohydrate; (4) specific therapy.

Oral Analgesia.—J. T. Gwathmey, discussing preliminary medication in connection with the administration of anesthetics, says "oral analgesia" may be used with assurance when morphine is contraindicated. It is especially useful in painful dressings or slight operations. The method of administration is as follows: One ounce of port wine is placed in a glass, and the "analgesic" in another glass. The patient takes a small mouthful of the wine, holds it about 15 seconds, rinsing the mouth so as to get the aroma in the upper air passages and the taste well established, and then swallows the wine. The "analgesic" is then taken, and is followed immediately by the remainder of the wine. Patients are able to take food and water shortly afterward, and even in patients much exhausted by infection there have been no deleterious after-effects. While it is well not to give the "analgesic" immediately after a meal, no special preparation of the stomach is necessary. The following formulæ have been used clinically with success:

1. Ether,
   Liquid paraffin, āā.....drams iv
   Aq. menth. pip. .....m v
2. Ether,
   Paraldehyde, āā .....drams ii
   Liquid paraffin .....drams iv

ORGAN THERAPY IN THYROID AND ALLIED DISORDERS.

BY JOHN ROGERS, M.D.,

NEW YORK.

THE material ordinarily employed for thyroid feeding is made by desiccation of the entire gland. The resultant powder has a variable content of iodine and of fatty and fibrous or other tissue, and in the drying process, which takes some time, may become contaminated with the more or less toxic products of autolysis. In addition, the original glands may be goitrous. Therefore, about fifteen years ago the (then) Department of Experimental Therapeutics in the Cornell University Medical College undertook an attempt to improve upon this somewhat crude medicament. It was soon found that the nucleoprotein material, which could be readily obtained from an aqueous extract of hashed fresh glands, was clinically much less toxic and far more generally beneficial and useful than the powder made from the entire dried organ. It consists always of the same kind of thyroid material, and must be made from fresh and not stale or decomposed or autolyzed glands, and can be standardized to contain always the same amount of iodine.

Of the pig, sheep, and beef thyroids which were tested, the pig glands were the most constantly normal in character, contained the most iodine, and seemed the most active and valuable in hypothyroid conditions, especially if the blood pressure in these cases was above normal. When the blood pressure was low the sheep thyroid nucleoproteins were equally good, and occasionally better.

In testing the comparative advantages of pig and sheep thyroid there was noted one very curious effect. A few individuals, who otherwise were objectively benefited by the pig nucleoproteins, developed a feeling of melancholy which was accompanied by a "teary" or lacrymose condition. A change to sheep thyroid would immediately dissipate the tears and induce smiles. Although this somewhat weird effect is uncommon, it can be so immediately changed by substituting the sheep for the pig thyroid that it seems to be real and not imaginary. The sheep thyroid glands contain less iodine than the pig, and show rather marked seasonal variations in this element, and are very frequently goitrous. As they are expensive, and sell by the pound, the temptations to use goitrous glands which may be as large as one's fist are obvious. The normal sheep thyroid gland is about the size of an almond. Extracts or derivatives of goitrous glands in our experiments were apparently inert. The beef thyroids contain the least iodine of the three, and clinically seemed of doubtful value and were soon rejected. The thyroid globulins which can also be obtained from an aqueous extract are richer in iodine than the nucleoproteins, but when tested clinically were much more prone to excite tachycardia or other unpleasant symptoms and, like the beef thyroids, were soon abandoned.

The nucleoproteins from the pig and sheep glands were finally selected as the best thyroid medicament, and their dosage standardized by their iodine content. This material was most conveniently mixed with some inert substance so as to make one grain tablets which contained in each 1 per cent., 2 per cent., 5 per cent., or 10 per cent., respectively, of iodine. This means approximately 1/100, 1/50, 1/20, or 1/10 grain of the pig or sheep thyroid nucleoproteins, which clinically for indications and dosage, is more or less equivalent to ⅛, ¼, ½, or one grain of the dried powder made from the entire gland. But, as remarked before, the thyroid nucleoproteins with their definite iodine content and freedom from foreign or autolyzed tissue are a much more accurate medicament and, clinically, seem much preferable to those in general use.*

As the thyroid nucleoproteins seemed so advantageous, the nucleoproteins of other endocrine organs were also tested. The indications for pituitary, parathyroid, adrenal, ovarian, or other organ feeding are by no means so clearly definable, nor are the results so striking as those of thyroid feeding. Nevertheless, there are at least some theoretical reasons, especially for adrenal feeding, and some symptoms which are capable of relief by the administration of the other endocrine organs, and in our tests nucleoprotein material seemed generally better and more efficacious than any desiccated entire gland.

The animal experiments which were started with the clinical tests showed that feeding the thyroid nucleoproteins by mouth stimulated the metabolism to about the same degree as did the dried entire gland when the dosage of iodine corresponded. But hypodermatically neither the nucleoproteins nor any of the coagulable portions of an aqueous thyroid extract excited any *immediate* response. The filtrate which remained after the removal of these substances was then boiled and thus, after some concentration, was more or less hydrolyzed and for lack of a better name was called the thyroid "residue." This liquid, when given subcutaneously or intravenously, excited prompt and vigorous reactions. It could be subdivided into active and inactive portions, but in the end it seemed that the

*These and the other preparations mentioned below are now generally obtainable through Schieffelin & Co., New York City.

original "residue," when concentrated to contain about 0.05 mg. of iodine per cc., was more active than any of its parts.

Tests were next made with an alcohol extract of the thyroid. Hashed fresh pig glands were extracted for several days with 95 per cent. alcohol which was evaporated by slow boiling and water then added until the iodine content was the same as that of the "residue," or about 0.05 mg. per cc. This alcohol extract had almost exactly the same physiological action as the residue or non-coagulable hydrolyzed aqueous extract of the thyroid. Clinically, about 5, 10, or 15 minims of either extract by mouth were found to be therapeutically effective. The thyroid residue has seemed most useful in hypothyroid conditions in which the more prominent symptoms were those of deficient functionation in the gastrointestinal tract, and especially when the blood pressure was much elevated. The alcohol extract seemed particularly useful in hypothyroidism which was accompanied by a sensation of subjective dyspnea or by any ill-defined pain without discoverable lesion which has the character of neuralgia. The question then arose as to the comparative advantages of the thyroid nucleoproteins and the liquid residue.

Experimentally, it was found, as is now more or less well known, that a thyroidectomized dog could live indefinitely and show no apparent change. But the administration of any thyroid material to the animals immediately increased the metabolism, and unless the experiment was soon stopped, the dog died. A normal dog, on the other hand, after the cessation of thyroid feeding rapidly recovered.* From these and other facts, the inference has been drawn that the feeding of thyroid (or for that matter of any other organ product) can be effective only after passing through the patient's own gland. If this is absent, as for example after double oophorectomy, organ therapy is probably useless or harmful. It seems to be necessary for the patient to possess at least some thyroid epithelium (or adrenal or ovarian as the case may be), and it must be capable of some functionation to permit the corresponding "feeding" test to be of any therapeutic value. These considerations bear upon the comparative advantages of feeding the thyroid nucleoprotein material or the liquid residue. In normal dogs the nucleoproteins produce their effects more or less slowly. The thyroid residue, on the other hand, excites an immediate reaction, and hence must be at least somewhat related to the gland's active principle. Hence, clinically and for therapeutic purposes, the thyroid residue should be indicated when there is reason to suspect an extreme functional incapacity in the patient's own thyroid epithelium. Such conditions might exist acutely after operative traumatism of the gland, or chronically in cases of long-continued hypothyroidism. Experimentally, the thyroid residue is a vigorous vasodilator and stimulant, particularly of gastrointestinal activity, and practically, as remarked before, it seems most useful in the chronic hypothyroid disturbances which are accompanied by high blood pressure, or by evidences of deficient gastrointestinal functionation, or by both of these conditions together. The thyroid nucleoproteins generally seem better in the more typical hypothyroid or myxedematous conditions.

*Unpublished experiments.

The symptoms which permit a recognition of the distinctions between hypo- and hyperthyroidism and the so-called mixed types of these disorders require some discussion of the physiology of the thyroid. The prevailing conception of this subject seems to be chiefly derived from the well-known effects of thyroid feeding upon the action of the heart. Because the administration by mouth of a few grains of the desiccated entire gland is so often followed by tachycardia, the average observer believes that the thyroid must, therefore, stimulate the cardio-accelerator nerve; and if it affects this nerve why not the whole sympathetic system? But he forgets that if the thyroid feeding is continued long enough there are added to the tachycardia, vasodilatation, sweating, and increased functional activity of practically the entire gastrointestinal tract. These latter phenomena are not traceable to stimulation of the sympathetic but to that of another group of nerves, namely the autonomic or vagus system. For the viscera, it should be recalled, apparently have a double nerve supply: one is the sympathetic proper, with its cervical, thoracic, and abdonimal plexuses, which, when stimulated, produce vasoconstriction and, as a rule, inhibition of functional activity. The other group of nerves is sometimes called the parasympathetic, or the autonomic, but would be more easily recognized if it were designated by the name of its most prominent and best understood member, or as the "vagus system." This vagus system (though, of course, the vagus itself does not supply the skin and all the blood vessels), according to electrical and chemical tests, produces vasodilatation, sweating, exaggerated heart action, and increased functional activity of the gastrointestinal tract, and all of these phenomena are accepted, together with the tachycardia, as evidences of the typical condition of hyperthyroidism. The atypical forms of the disorder are usually designated as such because the signs of autonomic or vagus activity are not prominent or are intermittent, or even entirely absent. For example, a patient with a "goiter" and more or less tachycardia and asthenia, but with headache, a pale dry skin and evidences of insufficient gastrointestinal functionation is generally now described as suffering from atypical hyperthyroidism, or from mixed hypo- and hyperthyroidism. That is, when the "vagus system" is inactive, as evidenced chiefly by the condition of the skin and gastrointestinal tract, and there is present more or less "goiter" and tachycardia, the disturbance is generally described as "atypical," or "mixed." Thus the clinical differentiation must be traced back to the visceral nerves and to the seemingly opposite functions which they are believed to perform. The impulses they convey can, perhaps, be more clearly visualized if they are expressed briefly as those of "drive" and "check." For the vagus and its allies in this system (the third, seventh, ninth, and eleventh cranial nerves, the visceropelvic nerve, and the vasodilating fibers) seem in general, by their power of dilating blood vessels and by their action in increasing functional activity, to "drive" the viscera to do their duty. The sympathetic, on the other hand, with its vasoconstricting properties

and its power mainly to inhibit the functions of the gastrointestinal tract, can be said to exert an influence which is that of "check." The chief clinical difference, then, between the typical and atypical forms of so-called hyperthyroidism consists in an excess of, or absence of, visceral and cutaneous "drive." The typical cases show a "drive" in vasodilatation and sweating and overacting, rapid heart, and in the excessive hunger ("vagus hunger" contractions of the stomach) and excessive intestinal peristalsis. The atypical cases, except for the tachycardia, show opposite signs, or an absence of drive, and generally also more or less headache. The typical or pure *hypo*thyroid cases are the same as the atypical *hyper*thyroids, except that there is no tachycardia. True myxedema differs from hypothyroidism only in the intensity of the failure of the "drive." The quiet pulse is more like a quiet bradycardia, and there is added more of the characteristic color and edema, particularly in the face. There are present almost no impulses of vasodilatation. The color is that of vasoconstriction.

To add to the difficulties of differentiation, there is now quite general agreement that these conditions are interchangeable. In other words, a case of typical hypo- may within a few weeks become a typical hyperthyroidism, and even have exophthalmos added; or the developments may take place in the reverse order. But if a sufficient number of these patients are observed for a long enough time there will be noted a rather definite sequence of events. For they all seem to begin with some kind of fatigue or with mental or nervous "strain" which is its psychological equivalent. This "worry" involves an effort of will in which the visceral "drive" to support the cerebral expenditure of energy is constantly accompanied by a "check" to restrain the impulse to relax or "run away." The result, especially in a nervous individual, who can be defined as one more responsive than the average to environmental influences, is a more intense exhaustion or fatigue than that induced solely by muscular effort. After this initial fatigue there follow the signs of hypothyroidism. If the conditions which induce fatigue continue, these signs more or less rapidly change to those of hyperthyroidism and still later there may be added exophthalmos. The mechanism which causes the latter symptom is still unknown, but it, like others, can be intensified by fatigue and relieved by rest. If recovery occurs there is always a more or less prolonged period of hypothyroidism after the tachycardia subsides before health is regained. But improvement is so constantly preceded and accompanied by rest, and the advancement from a milder to a more severe condition so constantly follows fatigue that the relationship seems obvious.

In experiments with the contractions of voluntary muscles, it has long been known that fatigue first affects thae functions performed by the nerve terminals of end plates. When these structures begin to fail the injection of a thyroid extract (the hydrolyzed residue or alcoholic extract) immediately restores the muscular vigor. But if the fatigue of the end plates is continued until their function is exhausted, then the thyroid injection is without result.* This indicates, of course, that the thyroid acts through or upon the end plates of voluntary muscles. But it acts only when these end plates are capable of at least some functionation. If the end plate for any reason is incapable of functionation then, clinically, there should be no result from thyroid feeding.

The effect of fatigue upon the involuntary nerve terminals has not been demonstrated, but there is every reason to believe that their functionation is governed by the same general laws. If, therefore, extracts of the thyroid can be shown to affect the driving terminals of the visceral nerves, then much of the physiology of the thyroid becomes explainable. And this has been accomplished* For the hydrolyzed thyroid residue or the alcoholic extract of the gland, apparently by acting through or upon the terminals of the vagus, increases the flow of the gastric secretion from ten to twenty fold and that of the pancreas to a somewhat less extent. They also seem, through the corresponding nervous mechanism, to increase the flow of saliva and of urine, and to stimulate the peristalsis of the stomach and intestine and the uterine muscle. In the course of these experiments it was noted that no material could be obtained from either the normal animal thyroid or from the pathological human hyperthyroid gland, which excited, at least for the usual two or three hour period needed for kymograph tracings, any appreciable degree of tachycardia.† But almost any thyroid derivative, when administered for a long enough time, will produce tachycardia. As this symptom under these conditions is accompanied by increased metabolism, it seems probable that the increased heart action of hyperthyroidism is merely an accompaniment of a generally increased chemical activity. The tachycardia seems *not* to be the result of direct stimulation of the cardio-accelerator nerve by the thyroid product.

Extracts of the adrenal gland show effects which are exactly opposite to those of the thyroid. That is, they stop the stimulation previously induced by the thyroid extracts. They act like atropine, but these adrenal derivatives apparently produce their inhibition by stimulation of the functions believed to be performed by the terminal filaments of the sympathetic or "check" nerves. This general inhibitory power of adrenal extracts does not seem to be dependent upon the vasoconstriction produced by their content of epinephrin. For visceral anemia is not evident and a 1:1000 solution of adrenalin has not nearly as much inhibitory power over the stomach as, for example, the adrenal nucleoprotein material which contains only faint traces of epinephrin. These adrenal nucleoproteins, by the way, are particularly active in decreasing the hydrochloric acid of the gastric secretion and in checking gastric and intestinal peristalsis (in dogs).

In the course of experiments to determine the effects of adrenal feeding it was noted that nearly all of the adrenal products or derivatives, except probably adrenalin, seemed to produce a very marked increase in the thyroid's content of iodine.‡

*Extracts of the parathyroid or adrenal glands or adrenalin act in this same way. *Amer. Jour. Physiol.* Vol. xlv, No. 2, January, 1918, p. 97.

Amer. Jour. of Physiol., Vol. xxxix, 1916, p. 345; 1918, xlviii, p. 79.

‡Unpublished experiments.

The hydrolized aqueous adrenal "residue" (made like the thyroid "residue") which is rich in epinephrin, seemed the most efficient preparation in this respect. In hyperthyroidism, the severity of the symptoms bears some proportion to the decrease of iodine per gramme of gland substance, and if this means that an increase of iodine signifies a retention of the thyroid product or a decrease in output, then the adrenal derivatives, particularly the adrenal residue, have the same inhibitory effect upon this organ as they do upon the stomach and pancreas. Thus practically all adrenal derivatives seem to act through or upon all of the terminal filaments of the sympathetic ("check") system.

From these observations it is possible to believe that the chemistry or metabolism of each organ is automatically accelerated or retarded by a constantly varying "drive" or "check" mechanism. That the product or secretion of the thyroid (and probably other organs) acts through or upon the terminal filaments of the vagus system and thus, in conjunction with the nerve impulse, forms part of the "drive." That the adrenal product acts similarly through the sympathetic terminals and thus constitutes an essential part of the "check," and because the thyroid and adrenal glands are both believed to be supplied by vagus and sympathetic filaments, it is not improbable that any excess of thyroid product normally produces, by stimulation of the adrenals, a check upon itself. The excess of adrenal secretion should return in the circulation to the thyroid and inhibit the latter's activity. Experimentally, as remarked before, adrenal feeding at any rate seems to increase greatly the thyroid's iodine content.

The simplest explanation of the so-called thyroid neuroses (and indeed of all the visceral neuroses, especially those of the stomach and intestines) involves fatigue and the probable effects of this influence upon the functions of the drive and check nerve terminals. At the outset, fatigue should impair the activity of both mechanisms. Later, with its continuation or increase, the preponderance of the deficiency might be manifested in an increasing failure of the drive, which in the case of thyroid disorders would explain the symptoms of myxedema; or in an increasing failure of the sympathetic or check nerve terminals which would leave the thyroid free from inhibition. The result should be hyperthyroidism. This sequence is more in accord with the observed facts than any primary and vicious overactivity of the gland or of the vagus system. Fatigue, however, is not the only influence known to cause failure in nerve terminals. Poisons or the toxins of bacterial infection produce similar effects. But, clinically, fatigue seems to be one of the most common causes of these neuroses, and for therapeutic purpose is always of great importance.

The narration of case histories to demonstrate the success of any particular kind of treatment is of little scientific value unless the cases can be identified as belonging to more or less definite clinical groups in which other experimenters can verify all the facts. Fortunately, the typical hypothyroid and the typical hyperthyroid disorders can be quite easily identified and the results, if the same medicaments are employed, can be readily confirmed.

Typical myxedema, though comparatively rare, is almost unmistakable. In my experience, however, it is not as easily curable as the text books state.

CASE I.—Mrs. M., age 57, housewife, states that fifteen years previously several well known physicians had told her she had myxedema, and since then she had constantly been taking thyroid tablets, at first with great benefit. Of late, however, the conditions seemed to have changed. If she took no thyroid tablets there were in evidence a general mental and physical asthenia with deficient gastrointestinal functionation and much somnolence. If she took enough thyroid to relieve these symptoms there were added a more unpleasant group. The weakness, if anything, was made worse and there were palpitation and breathlessness, with nervous irritability instead of lethargy.

Physical examination showed the charcteristic facies with the typical ivory pallor and puffy eyelids; some dense edema; pulse rate 54, temperature 97°, respiration 18, weight 174, blood pressure 180. Blood and urine examination showed a slight anemia and a trace of albumin with a few hyaline casts.

June 5, 1915. A trial of 5-grain desiccated thyroid tablets t.i.d., resulted after three days in raising the pulse rate to 120 and a change from sluggish quietude tto a nervous restlessness. The blood pressure remained at 180-190. Weight 170, or a loss of 4 pounds. The desiccated thyroid was discontinued.

June 20, 1915. The signs of hyperthyroidism have disappeared and those of myxedema again prominent. Pulse rate 60, blood pressure 180, weight 172. A tablet containing 2 per cent. of the (pig) thyroid nucleoproteins was given every two hours.

June 25. No hyper symptoms and some improvement in those of the myxedema. Pulse rate 65, blood pressure 160, weight again 176. Medication increased to tablets containing 5 per cent. of the thyroid nucleoproteins every 2 hours.

July 2. No nervous irritability. Perceptible subjective gain. Pulse rate 70, blood pressure 150, weight 178. Medication increased to tablets containing 10 per cent. of the thyroid nucleoproteins.

July 15. Pulse rate 70°, respiration 20, blood pressure 140, weight 178. The puffiness of the eyelids has nearly disappeared. There is some color in the face. The skin is about normal, though still rather dry. The digestion is satisfactory and the subjective symptoms have practically disappeared.

May 3, 1920. This patient is active in "social service" work, but has to take 8 to 10 tablets daily of the 10 per cent. thyroid nucleoproteins. Even a much larger dose does not excite the dreaded hyper signs. While resting or on vacation, 4 or 5 of the 10 per cent. tablets seem sufficient. Any marked degree of activity, especially of nervous strain, induces an asthenia which can be relieved only by increasing the number of tablets.

Discussion:—Some cases of myxedema, especially if the blood pressure is higher than usual, if given sufficient desiccated thyroid to relieve the symptoms, will develop the even more troublesome signs of hyperthyroidism. If, however, the form of the thyroid medicament is altered to the nucleoproteins of the gland, the evidences of overdosage or change from a bad to an even worse condition has not in my experience occurred.

The following is an example of a very large group of cases which pass under the name of "neurasthenia," "nervous prostration," "nervous indigestion" or incipient or typical hypothyroidism. The condition seems really to be the result of too much work by too frail an organism, or a fatigue presumably of both the drive and check mechanisms. The key to the therapeutic problem is first rest, and next the psysiological aid of the drive which can be supplied by the right kind of thyroid feeding.

CASE II.—Miss A., age 19, telephone operator. Referred to me with a diagnosis of incipient hyperthyroidism and probably in need of operation. She has been unable to perform her regular duties for six weeks.

Complains chiefly of being "weak, tired, and nervous"; weeps easily and frequently; many headaches; "palpitation" and "breathlessness" are troublesome, especially after the least exertion or excitement. The palpitation of the heart often occurs on going to bed. Sleeps poorly and with bad dreams; has anorexia, gaseous indigestion, constipation. Physical examination shows a rather thin, poorly-nourished, and evidently "nervous" individual. Pallor noticeable, skin dry, hands cold. There is a slight thyroid enlargement which is perceptible to sight and touch. Tremor of the extended fingers. Pulse rate evidently "irritable," and 100-110 at first, but after sitting and talking quietly a few minutes it was counted again and found to be 80. Blood pressure (systolic) 110. Weight 120. Blood examination showed 95 per cent. hemaglobin. Cell count normal. Urine normal. No detectable visceral defect.

Diagnosis.—Chronic hypofunctionation of the vagus system and probably also of the thyroid.

Treatment.—November 10, 1919. When advised to take every two hours a tablet containing 2 per cent. of sheep thyroid nucleoprotein material, she manifested some reluctance as she said the thyroid tablets previously recommended had made her much worse. Finally the medication was accepted. In addition she was told to lie down an hour before and after meals and to be on her feet not more than fifteen minutes at a time and to be in bed at 9 p. m.

November 17, 1919. Reports one week later with considerable subjective improvement. Is much less "weak and tired and nervous." No headache. Appetite, digestion and sleep are better. No palpitation. Pulse rate 76 to 80, but still somewhat "irritable." Blood pressure (systolic) 120. Weight 123, or a gain of 3 pounds. Advised to double the amount of 2 per cent. sheep thyroid nucleoprotein tablets.

November 24, 1919. Examined and found practically normal, but still easily fatigued. Weight 126, or a gain of 6 pounds in two weeks. Returned to work, but advised to continue two of the tablets of 2 per cent. sheep thyroid nucleoproteins five or six times daily for months.

Discussion:—The history was that of constant work under much "nervous strain" followed by symtoms which indicated a fatigue of both the vagus and sympathetic systems. There was an evident lack of mental inhibition or "check" in the emotionalism, and of muscular "check" in the tremulousness and irritable pulse rate. The lack of "drive" showed chiefly in the deficient cutaneous vasodilatation and muscular energy, and the deficient gastrointestinal functionation. If the thyroid is part of the "driving" mechanism, then thyroid feeding with the least "toxic" thyroid material should be the logical and physiological treatment. Rest, of course, is essential.

The variable effects of the different thyroid preparations are difficult to explain, but real and important, and can probably be best understood from case histories.

CASE III.—Miss B., age 20, saleswoman. Unable to work for two months. History almost exactly like that of CASE II. Complains chiefly of anorexia and some nausea, and of much epigastric distress after eating, with gaseous indigestion and eructations and constipation. Amenorrhea for three months. She is also "weak, tired, and nervous" and emotional; many headaches, especially in the morning. She had been treated for some time for "stomach trouble" without gain, and had finally gone to a dispensary where a trial of 1 grain thyroid tablets had excited marked palpitation and nervousness. She later had had the Goetsch test with adrenalin, which she said was positive. A "goitre" had been noted since puberty, and recently had increased in size. A thyroid operation had been advised.

Physical examination showed a tall, poorly developed, and poorly nourished young woman. Noticeable pallor. Dry skin. Moderate, soft, perfectly symmetrical enlargement of the thyroid to about triple the normal size. Pulse rate irritable and 120-130 at first, but after lying at rest for half an hour it was counted at 80. Blood pressure (systolic) 145, weight 132. Blood count and hemaglobin normal. Urine normal.

Diagnosis.—Chronic hypofunctionation, probably of the visceral vagus system, and also of the thyroid.

Treatment.—April 25, 1919. Rest, as in Case II, and every two hours the tablets of 2 per cent. thyroid nucleoprotein.

April 28. Reports with little or no improvement and with some increase in the "nervousness" and "palpitation." Tablets discontinued and 5 to 10 drops of the liquid thyroid residue given every two hours by mouth.

May 5, 1919. Reports that she feels exceedingly tired, but is sleeping and eating better, and has almost no indigestion. Pulse 76, blood pressure 110, weight 134, or a gain of 2 pounds. Thyroid residue (10 to 12 drops) by mouth continued, and the tablet containing 2 per cent. of thyroid nucleoproteins added to the medication.

May 14. Almost no indigestion; appetite improved. Complains only of being weak and easily tired. Sleeps better. Pulse 76, blood pressure 115, weight 138. Thyroid residue and 2 per cent. tablets discontinued, and in their place there was given the tablet of 5 per cent. sheep thyroid nucleoproteins to be taken every two hours indefinitely. Returns to work with the warning to regard lack of sleep, nervous irritability, or indigestion as the initial signs of a recurrence of the "overstrain" or thyroid disorder.

CASE IV.—Mrs. C., age 30, machine operator in a "sweat shop." The history and physical examination are almost exactly the same as in Cases I and II, except that the chief complaint is of an ache or pain in the region of the thyroid gland, with a sensation of tightness as of a band or cord around the neck. After exertion or excitement this "tight feeling" causes difficulty in swallowing. Had been told to have the thyroid excised. In addition, there were the usual complaints of "lack of drive" in many organs, or hypothyroidism.

Physical examination showed only a slight, soft, symmetrical enlargement of the thyroid gland. Pulse rate 70-80. Blood pressure 130. Weight 128. Blood and urine normal.

Diagnosis.—Chronic hypofunctionation of the vagus system, and probably also of the thyroid.

Treatment.—March 12, 1918. Cessation from work for one week, with as much rest as possible. Thyroid residue, 10-12 drops every two hours.

March 15, 1918. The discomfort and pain in the throat have disappeared. Appetite, digestion, and sleep improved. Tablets of 10 per cent. thyroid nucleoprotein substituted for the liquid residue.

March 23. Compelled to return to work, but though still easily fatigued can continue her occupation without the distress in the throat as long as she takes the thyroid tablets.

Discussion:—Cases II and III both had, in addition to the accepted signs of hypothyroidism (which are chiefly those of deficient functionation in the vagus system), an "irritable" pulse rate. This is generally supposed to indicate a "mixed" hypo- and hyperthyroidism, and yet it can be relieved by the right kind or least "toxic" form of thyroid feeding. The nucleoproteins acted well in Case II and did not in Case III in which deficient gastrointestinal functionation was the most distressing complaint. But after feeding the liquid thyroid residue for a short time there was relief of the indigestion and decrease of the blood pressure. The nucleoproteins then acted well and continued the improvement. In Case IV, the pain or ache in the region of the thyroid, or a "choking," "constricted" sensation, almost always accompanied by at least a perceptible enlargement of the gland and other signs of hypothyroidism, is very common. It cannot be hysterical or imaginary because it is regularly relieved by rest and by feeding preferably the thyroid residue. This discomfort or pain in the throat is apparently not

due to mechanical pressure, as evidenced by the following history.

CASE V.—Mrs. W., age 42. After a strenuous period of Red Cross and other social war activities, noted a circumscribed swelling in the right lobe of her thyroid gland. This had slowly enlarged for the past six months, and is always more noticeable during menstruation or after exertion or excitement. For the past month has been "weak, tired, and nervous," with rather constant "palpitation and breathlessness." Her neck for years has been "full," and formerly there were many headaches, especially after any fatigue. There used to be much anorexia, dyspepsia, and constipation. Of late, the headaches have disappeared and the appetite and digestion have improved. Much alarmed about the disfiguring "goiter" and about the feeling of "constriction" and "pressure" in the thyroid region.

Physical examination showed a well nourished woman, good color, flushes easily; a rather firm, circumscribed, globular tumor, apparently an adenoma or cystadenoma, some two inches in diameter in the right lobe of the thyroid. The rest of the gland seemed slightly enlarged throughout, and except for this single tumor, of an even consistence throughout. Tremor in extended fingers. Pulse rate 110-120, and in repose 100. Blood pressure 140. Weight 156. Blood and urine and other examinations were negative.

Diagnosis.—Mild incipient hyperthyroidism, or mixed hypo- and hyperthyroidism, probably dependent upon a so-called "toxic adenoma."

Treatment.—Nov. 18, 1919. Rest, and the tablets containing 2 per cent. of the sheep thyroid nucleoproteins every 2 or 3 hours. Result: Some relief of symptoms, especially of the feeling of pressure and constriction of the throat. But unless a very quiet mode of life were pursued, with much rest, the nervous and emotional irritability and the palpitation immediately reappeared. The pulse rate was regularly about 100. Therefore, on February 4, 1920, under local anesthesia with 1 per cent. novocaine, I "shelled out" of the right lobe of the thyroid a well encapsulated, solid, globular adenoma about two inches in diameter. Both superior vessels were at the same time tied and cut, and a section for histological study taken from the tips of both thyroid lobes. The pathologist's report later stated that the lobes appeared normal, except that the alveoli were rather large and the colloid matter stained palely. The tumor was an adenoma with considerable hyperplasia.

February 15. The nervous and vasomotor irritability had promptly subsided. Pulse rate 72. Blood pressure 120. Condition normal, except for a rather noticeable pallor. A perceptible, symmetrical thyroid and some natural weakness. Goes to Atlantic City for two weeks of rest and quiet. Condition that of mild hypothyroidism.

April 2. States that she returned perfectly well to take up her usual activities and again was easily fatigued and had a "tight feeling" in her throat. Her family physician had advised some 1 grain thyroid tablets which, after a few days, had seemed to make her very nervous and short of breath and had not relieved the pain in the thyroid region. This peculiar symptom alarmed her with fear of recurrence of the "goitre." Physical examination showed the usual transverse scar and the thyroid slightly smaller, if anything, but still perceptible, and of even soft consistency. Pulse rate 110. Blood pressure 120. Weight 160.

Diagnosis.—Recurrent mild hyperthyroidism, probably due to injudicious thyroid feeding.

Treatment.—April 2. The commercial thyroid tablets were discontiuued for three days, and also every unnecessary activity.

April 6. Reports that the nervousness has disappeared and the constriction of the throat is less but recurs after any exertion or excitement. Pulse rate 76. Blood pressure 120. Advised that the tablets of 5 per cent. sheep thyroid nucleoproteins be taken every two hours, but stopped if they excite any nervousness or palpitation.

April 16. Reports much improved. The disagreeable throat sensations promptly disappeared. Much less easily fatigued.

Several weeks later she reported again that she had had to continue the thyroid feeding, as after interrupting it a few days she felt "tired." Advised to continue the tablets indefinitely.

Discussion:—This last patient gave a history strongly suggestive of a mild "hypothyroidism" which had existed for years. Then after prolonged exertion and excitement there developed a so-called toxic adenoma and symptoms of mild hyperthyroidism which could only be entirely relieved by operation. The distressing "constriction" or "pressure" in the thyroid region could not have been due to the mechanical pressure of the tumor because it returned after its removal, and disappeared after the thyroid feeding. In the preceding case, with the same symptom of "constriction" or "pressure" pain in the thyroid region, there was never any tumor and only a very slight enlargement of the thyroid.

After operation in Case V, the patient apparently returned to her original condition of mild chronic hypothyroidism, which was then changed to hyperthyroidism by feeding the usual commercial preparation of thyroid. The less "toxic" nucleoprotein material did not excite these signs and did relieve all the symptoms. The previous patient, however (Case IV), could not even take the thyroid nucleoproteins until a beginning was made with the hydrolyzed thyroid residue. Whether this has anything to do with the functional activity of the digestive system it is impossible to say, but if the predominant symptoms are those of hypofunctionation of the gastrointestinal tract, the liquid thyroid residue seems generally more beneficial than the nucleoprotein tablets. After a preliminary improvement with the residue the nucleoproteins will generally prove beneficial. The most definite sign of hyperactivity of the thyroid is believed to be furnished by the calorimeter. Even when this proves that the rate of metabolism is above the normal, the thyroid residue may not be counterindicated, as shown in the following case.

CASE VI.—Miss L., age 38, presents the usual symptoms of mild exophthalmic goitre, except a rather marked pallor (no anemia). Poor appetite and deficient functional activity of the gastrointestinal tract (gaseous indigestion and constipation). General condition good. Slight but unmistakable exophthalmos, small firm goiter. Pulse rate 110-115. Temperature 99-100. Blood pressure 180. Weight 156. Tremor in extended fingers. Goetsch adrenalin test had been positive. Calorimeter test (Benedict apparatus) 20 per cent. above normal.

Treatment.—March 2, 1920. Because of the general good condition, the marked pallor, the apparent deficient functionation of the gastrointestinal vagus, and the rather high blood pressure, a trial was made of feeding the thyroid residue at first in five, then ten, drop doses by mouth every two hours. No change in diet or mode of life. She had been practically in bed for the previous six weeks.

March 12. Considerable subjective improvement, especially in digestion. Pulse rate 90-100. Temperature 98.4°-99.5°. Blood pressure 150. Tremor less marked. Calorimeter test had decreased to 8 or 10 per cent above normal. Thyroid residue continued.

March 19. Out of bed most of the day. Exophthalmos just perceptible. "Goiter" softer. Pulse rate 80-90. Temperature 98.4°, and after awakening in the morning slightly subnormal. Blood pressure 115-120. Weight 160. The only subjective symptoms were asthenia and some wakefulness relieved by a mild hypnotic. Medication changed from the thyroid residue to the tablet containing 5 per cent. of the sheep thyroid nucleoproteins.

She has resumed work as a private secretary, but has

to continue the thyroid nucleoproteins. If omitted for any length of time the general asthenia returns.

Discussion:—There was every evidence, in the clinical signs and in the increased metabolism, of hyperthyroidism, yet "feeding" thyroid seemed to effect a cure. Although the opportunity to repeat the crucial calorimeter test in conjunction with the thyroid residue medication in a case of apparent hyperthyroidism which showed exophthalmos has not again occurred, this clinical experience has been noted several times. That is, patients with all the clinical evidences of hyperthyroidism and with more or less of the temperature which accompanies increased metabolism may be benefited by this form of treatment, and when in doubt as to the exact indications a cautious trial of the medicament in 5 or 10 drops doses is at least free from danger. If it intensifies any symptoms it can be stopped and the symptoms will soon disappear.

The following experience with the thyroid residue shows how it may be of value in the so-called postoperative exacerbations of hyperthyroidism.

CASE VII.—Miss C., age 42, showed multiple toxic adenomata of the thyroid with symptoms of marked hyperthyroidism and some tracheal pressure.

Oct. 5, 1917. Enucleation of several large adenomata from both lobes of the thyroid. Ligation of both superior vessels. Much traumatism of the gland. There remains probably about one-half of the normal amount of thyroid tissue.

Oct. 7, 1917. Severe reaction. Headache, much nervous irritability, scanty urine. Pulse rate 160. Respiration 50. Temperature 104°. Thyroid residue, 20 minims given by hypodermic three times at four-hour intervals.

Oct. 8, 1917. Pulse rate 120. Respiration 30. Temperature 101°. Headache, nausea, and nervousness much improved. Skin moist. Ten drops of thyroid residue given by mouth every 2 hours for four days.

Oct. 13, 1917. Condition practically normal. Left the hospital at the end of four weeks taking the tablets of 2 per cent. sheep thyroid nucleoproteins with apparent benefit.

March 20, 1919. Reports without any perceptible thyroid enlargement or any evident functional thyroid disturbance. But complains bitterly of an aching pain in the right arm and in the shoulder, and "shortness of breath." Respiration has a "sighing" character with a constant effort to obtain "more air." Some gaseous indigestion and constipation. Blood pressure 120, pulse rate 70. Urine negative. No gross abnormality could be detected. A tentative trial of the liquid thyroid residue and then of the nucleoprotein tablets produced some relief of the gastrointestinal symptoms, but not of the troublesome "neuralgia" nor of the peculiar subjective dyspnea. An alcoholic extract of the thyroid (pig), made as described previously but with only one-half of the iodine content of the thyroid residue, was then given by mouth in 10-12 drop doses every 2 hours.

After the first 24 hours the "neuralgia" had disappeared and the dyspnea was less. Two days later all symptoms had disappeared. The alcoholic thyroid extract was continued for a week, and the tablets of 10 per cent. sheep thyroid nucleoproteins then substituted. Since then if she suspends the thyroid feeding for any length of time and then indulges in much social activity, the neuralgia recurs, if not in the arms, in the leg or often in the back or occipital region. This alcoholic thyroid extract promptly relieves it.

Discussion:—The threatening reaction which followed the operation upon the thyroid seemed to be greatly relieved by the thyroid residue. Its use was suggested by the apparent deficient functionation in the gastrointestinal vagus system, and because it seemed improbable after the violent manipulation of the thyroid that this gland was capable of any activity. The result seemed to justify the assumptions, and the experience has been repeated, although always with caution, in many similar cases. In a few instances, but by no means in all of the postoperative toxemias, the thyroid residue has seemed to be life saving. Several years later, this patient presented no evidences of thyroid abnormality except the history. The complaint was chiefly "neuralgia" and subjective dyspnea. Neither symptom was affected by the (aqueous) thyroid residue nor by the nucleoprotein tablets. The latter seemed even to increase the dyspnea. But the alcoholic extract of the thyroid promptly relieved both the dyspnea and the neuralgia. I can offer no explanation for the different effects of these different thyroid preparations. I can only state that if the symptoms of deficient activity in the vagus system are very suggestive of thyroid hypofunctionation, and one kind of thyroid medicament fails, another thyroid preparation may succeed. The alcoholic extract of the gland is very useful for these vague but evidently distressing "neuralgias," and also for the rather peculiar "dyspnea" which is generally regarded as hysterical.

The typical hyperthyroid cases show an apparent overactive functionation or "vagotonia" of the entire autonomic or "driving vagus system." These symptoms, as remarked above, are more easily explained as really dependent upon a deficiency in the chromaffin or general sympathetic-adrenal "check" mechanism. Although the majority of these patients require more or less extensive operation, a few can be greatly benefited by one or another kind of adrenal feeding. Experimentally, as remarked before, this increases the iodine content of the thyroid. In hyperthyroidism the iodine content of the gland is less than normal. Theoretically, also, adrenal feeding should stimulate or increase the functionation of the apparently deficient check mechanism.

CASE VIII.—Miss H., age 18, after a strenuous "coming out" season, with much excitement and insufficient sleep, showed mild but perfectly typical symptoms of exophthalmic goitre. Has been resting and taking iodine and ovarian tablets (for scanty and painful menstruation) with bromides and sedatives for three months without improvement.

Physical examination Sept. 20, 1919, showed slight but unmistakable exophthalmos. Moderate-sized, soft, symmetrical thyroid enlargement. Pulse rate 120-130. Blood pressure 120. Weight 118. Temperature 99.1°. Tremor pronounced, with "jerky" movements. Good color, flushes and pales easily. Moist skin, appetite abnormally good. Bowels move twice or thrice daily. Cannot sleep before midnight. Fatigues easily, both mentally and physically.

Treatment.—Advised 10 drops of the adrenal residue by mouth in water every two hours. No change in the mode of life, which for the past three months had been one of seclusion, and only about four hours daily out of bed.

Oct. 15, 1919. Appreciable though slow gain in the pulse rate, now 110-115, and especially in the weight, now 128. Subjectively less "nervous." Adrenal residue continued.

Nov. 19. Continued improvement. Pulse rate 90-100. Weight 132. Sleeping more normally. Bowels move once instead of several times daily. Up and about the greater part of the day. Adrenal residue continued.

Dec. 10. The exophthalmos is almost imperceptible, the goitre smaller, tremor much less, no jerky movements. Pulse rate when quiet 80-90. Weight 136. To the medication with the adrenal residue there was now added iodine after meals in the form of 1 grain

iodide of iron pills (which in these cases seems the best tolerated of any iodine preparation). Iodine in the form of small doses of iodide of potassium had been given during the previous summer without effect.

Dec. 15. Following the administration of the iodide of iron the "goitre" has enlarged—this is accompanied by a "tight feeling in the neck." The iodide of iron was stopped, adrenal residue continued.

Dec. 17. Goitre again soft and smaller, no feeling of constriction. The 1 grain pills of iodide of iron given once daily every other day. Ten drops of the adrenal residue six or seven times daily. There followed no ill effect and apparently much gain.

Jan. 15, 1920. About normal, except for a perceptible thyroid enlargement; a rather irritable pulse rate which when lying down was between 70 and 80. Weight 142. Asthenia still present. The iodide of iron was now given once daily, and later twice, and with apparent benefit. The adrenal residue as before.

March 10. Discharged as well.

Discussion:—The administration of the adrenal residue without other change in the treatment seemed very beneficial. Iodine has to be used with caution in these cases, because of the danger of an acute exacerbation of hyperthyroidism. But this risk can always be escaped if, as in this case, the preliminary swelling of the gland with the sensation of constriction are noted and the iodine stopped. It had been given in the preceding summer without any appreciable effect, but after a preliminary treatment with adrenal feeding the iodine then seemed useful.

CASE IX.—Mrs. M. dates her present illness from the effects of a hysterectomy for fibroid uterus at the age of 34, in 1906. Both ovaries had been preserved. During the Spring of 1908 she developed typical rather severe symptoms of hyperthyroidism, and apparently recovered after the use of antithyroid serum. Remained well for nine years.

Nov. 10, 1917. After a period of hard work and worry again shows somewhat irregular signs of hyperthyroidism. No exophthalmos; brownish coloration of the skin, which is moist; small, firm, symmetrical "goitre"; pulse rate 110-120; blood pressure 210; weight 104; blood and urine negative; tremor present, with nervous, jerky movements; good appetite; bowel movements loose and 5 or 6 daily; has been practically in bed for two weeks and has lost 8 pounds.

Treatment.—Nov. 10, 1917. Diet and mode of life unchanged. Advised 1 grain tablets containing 10 per cent in each of adrenal nucleoproteins, 2 every 2 hours.

Nov. 17. Considerable improvement, especially in the "colitis." Bowel movements 2 instead of 5 or 6 daily. Pulse rate 90-100; blood pressure 180; weight 106. Less nervous, less hungry. Adrenal nucleoproteins continued.

Nov. 24. Continued gain. Pulse rate 80-90; blood pressure 170; weight 108. Up and about the house.

Dec. 2. Practically normal again, except for the "goitre." Somewhat irritable pulse rate (after resting 76-80, after any exertion 90-100), and blood pressure 150. Weight 107. The continuation of the adrenal nucleoproteins for another month with a quiet mode of life seemed to restore the usual good health.

A year later, however, after "moving," almost the same condition returned, with tachycardia, signs of a painless enterocolitis and high blood pressure (220). These symptoms were again apparently all relieved by feeding the adrenal nucleoproteins. The blood pressure returned to 150.

Discussion:—The adrenal nucleoprotein material, because of its low content of epinephrin (mere traces), was employed instead of the adrenal residue which is very rich in epinephrin. There are no experimental data to justify any assumption that the product of the adrenal gland has any lasting effect in raising (or lowering) blood pressure. Nevertheless, clinically, in these somewhat irregular hyperthyroid conditions with *high* blood pressure, especially when the bowels are loose, the adrenal nucleoprotein material will be found very useful. It seems to lower the blood pressure and improve the gastrointestinal functionation and benefit the general condition. Its only ill effect is occasionally an intensification of the feeling of "nervousness." Then it can be stopped. On the other hand this material had been employed in the College dispensary for the treatment of some rather vague cases of "neurasthenia," or general weakness, without any discoverable lesion except a constantly and noticeably *low* blood pressure. The improvement has been accompanied by a rise in blood pressure.

There are many gastric neuroses (occurring chiefly in men) which seem to be closely analogous to the thyroid neuroses (occurring chiefly in women). These disturbances are not generally considered among the problems of organ therapy, yet they are very susceptible to this form of treatment. And there is good reason for it because of the more or less definitely proved functions of the nerve supply of the stomach. Thyroid extracts stimulate the vagus terminals and the adrenal extracts, those of the "check" or sympathetic system. Consequently, adrenal feeding should be beneficial in cases of gastric hyperfunctionation and thyroid feeding in the opposite conditions.

CASE X.—Mr. F., age 44, mechanic, had suffered from epigastric distress for more than a year with, latterly, occasional vomiting (no blood). Has lost 30 pounds in weight. Pain is worse before than after eating, and latterly awakens him soon after midnight. Relieved by sodium bicarbonate. Constipation.

Physical examination: Somewhat emaciated, nervous type; otherwise negative. Test meal showed total acidity 115, free HCl 40. *X*-ray examination reported a probable pyloric ulcer.

Exploratory laparotomy May 28, 1920, revealed no gross abnormality of the viscera. Recovery uneventful. One week later the epigastric distress was nearly as troublesome as formerly. Test meal, June 11, 1920, showed total acidity 110, free HCl 40.

Treatment—Two one-grain tablets, in each 10 per cent. of adrenal nucleoproteins, given every two hours. "House" diet. Patient about the wards.

June 18, 1920. Considerable subjective improvement. Constipation much relieved. Test meal; total acidity 80, free HCl 26. Adrenal nucleoprotein tablets continued.

June 25. Feels quite well. No more gastric distress. Gained 3 pounds. Test meal: Total acidity 58, free HCl 8. Dismissed with the advice to continue the adrenal nucleoprotein tablets indefinitely, and to be careful about fatigue and overwork;.

CASE XI.—Mr. B., age 56, mechanic, has had epigastric distress with belching of gas for several years. No night pain. Poor appetite; some nausea; constipation; has lost about 10 pounds in the last six months; easily fatigued; wakeful. Appendix removed without benefit a year ago. Sent to hospital with diagnosis of gastric ulcer.

Physical Examination.—June 7, 1920. No apparent thyroid abnormality; fair general nutrition; *x*-ray of stomach negative. Test meal showed total acidity 20, free HCl 8.

Treatment.—Rest in bed; "house" diet; and every two hours mxx of thyroid residue by mouth.

June 14. Considerable subjective improvement. Less gas; less constipation. Test meal: total acidity 30, free HCl 14. Up and about the ward.

June 22. No discomfort, but still some "gas." Eats and sleeps well. Bowels regular. Gained 5 pounds. Test meal: total acidity 42, free HCl 18. Leaves with the substitution for the liquid thyroid residue (which easily decomposes) 1 grain tablets containing in each 10 per cent. of the thyroid nucleoproteins,

One month later there were no complaints.

There is another gastric neurosis which gives practically the same subjective symptoms as that accompanied by hyperacidity and pylorospasm. The objective findings, however, are normal except for some hyperperistalsis. This disorder can be relieved by rest, with pancreatic feeding in the form of trypsin, or trypsin combined with bile or bile salts.

As regards pituitary, parathyroid, ovarian, and other organ therapy, case histories could be narrated to show the value of the treatment. But these patients cannot as yet be classified in easily recognizable clinical groups like those who show an excess or deficiency of "drive" in one or more organs. Their symptoms are almost entirely subjective, and the changes induced by the medicament are generally incapable of objective demonstration. Or they occur so slowly as to suggest error in observation and so, for scientific evidence are practically valueless. Hence it is only possible to state didactically that there are many individuals, especially those having or having had some thyroid or gastric abnormality, who suffer from headache. This symptom can sometimes be relieved only by feeding pituitary, parathyroid, or ovarian material, and the nucleoproteins of these glands, as remarked before, will generally be found more efficacious than the desiccated entire organ. The "residue" of the pituitary or parathyroid glands (made like the thyroid or adrenal residue) showed no clinical advantages in our experiments over the nucleoprotein material and was, therefore abandoned. The ovarian "residue" seemed, however, at times to be efficacious when the ovarian nucleoproteins failed.

Some patients, especially those with hypothyroidism and poor general nutrition, who complain chiefly of asthenia, will continue "weak" unless the pituitary nucleoproteins are added to the thyroid medication. The pituitary or the parathyroid also seems helpful when there is an apparent asthenia or "lack of drive" in the small or large intestine. For functional dysmenorrhea, menorrhagia, or amenorrhea the ovarian nucleoproteins, or the (hydrolyzed aqueous) ovarian residue, have seemed preferable to any other form of ovarian medicament. But thyroid, or even pituitary, feeding is sometimes more efficacious, or a combination of thyroid and ovarian, or of pituitary and ovarian, feeding. The indications for and the results of treatment are as yet so vague and variable as to bring the whole matter of organ therapy into disrepute. This is partly due to the hitherto ill-defined symptomatology, and partly to the uncertain and unsuitable character of the medicaments. But there is now reasonably good evidence for believing that the products, at least of the pituitary, parathyroid, thyroid, and adrenal glands, act through or upon the terminal filaments of the involuntary and possibly the voluntary nerves. Hence, at least, some disturbances of function can be traced back to their source. The next problem is to reenforce and not impair the primary weakness, for it is safer to assume from all the available facts some original defective or deficient functionation, either secretory or nervous, rather than a causeless and vicious overactivity. For supplementing an organ's defective or deficient product it is more or less reasonable to administer the nearest available approach to this product, and one that experimentally produces demonstrable effects where theoretically they should occur, is probably better than the crude material consisting of the entire desiccated organ.

177 East Seventy-first Street.

STATE MEDICINE AND THE POETIC DOCTOR.

By JOHN J. A. O'REILLY, M.D.,

BROOKLYN, N. Y.

CHAIRMAN, NEW YORK STATE ASSOCIATION OF THE MEDICAL AND ALLIED PROFESSIONS; ASSISTANT, DEPARTMENT OF NERVOUS AND MENTAL DISEASES, KINGS COUNTY HOSPITAL; MEMBER OF THE NEW YORK BAR; LECTURER IN LEGAL MEDICINE, BROOKLYN LAW SCHOOL OF THE ST. LAWRENCE UNIVERSITY.

A DEFINITION is:—Building a fence of words around a fact which separates it from every other fact. Here are some timely ones.

Order is the harmonious relation of things which exist.

Law is a Rule of Order; it affirmatively specifies that which is right and meet and just and permissible and preservative of harmony and it negatively forbids that which is wrong and subversive of harmony. The Law which governs the harmonious relation of our Earth to the Planetary world is as intangible as the law which governs the conscience of a man, but the law which governs the abuse of that conscience by man in his relations with his fellows proceeds from the minds and hearts of those fellowmen and takes the form of a collective contract or agreement which specifies the rights and duties which may be enjoyed or must be fulfilled; its foundation is what we call a Constitution without which Society or the State, as such, can not exist: Lincoln crystallized this when he asked the second part of the question (*a*) Can a nation continue to exist half slave and half free? (*b*) Can a State, prior to the adoption of a constitution, forbid slavery within its borders?

To provide physical media for the expression of government the collective parties to that Constitution devise the Administrative, Legislative and Judicial Branches of Government and ordain that each shall be separate and distinct, that neither shall usurp the function of the other but that the trinity of function shall *be* the government; and to insure order to themselves and posterity the Collective Contractors reserve to themselves and those who legitimately follow, the right to determine the form of government and the media of its expression: The perfection of such organized government is our own beloved United States of America and its gloriously inspired Constitution. *You* probably know these things, but there are a lot of people who have either forgotten them or deliberately ignored them in their scramble for *uplift*.

THE POLICE POWER OF THE STATE.

Man is weak and prone to error; it would be humanly impossible for every act which proceeds from human impulse to be made the subject of statutory decree, therefore the power, vested in the Judiciary to interpret the meaning of Legislative Acts and their enforcement by the Administration, is made capable of a degree of elasticity to maintain the balance of abstract Justice; in the olden days this liberal interpretation was vested in the

King's Conscience and has come down to us as Courts of Equity or the Equitable Powers of the Law Courts: This supreme function is exercised through what is known as the Police Power of the State, under the doctrine of Public Policy, and it is with the *police power of the State* that we have to reckon in considering the practical operation of such miscalled *welfare* legislation as Compulsory Health Insurance, State Medicine, the National Socialization of Medicine, Coercive Re-Registration Acts under the specious title of "Medical Practice Acts," Administrative Right of Search (Narcotics and Alcohol) with a "tin badge" as authority in lieu of the Judicial Search Warrant, etc., etc., etc.

THE DUTY OF THE INTELLECTUALS.

"All men are created equal," says the Declaration of Independence, but we know that heredity, education and environment modify the social and civic and economic equality and produce classes precisely as one acorn will develop into a sturdy oak while another will produce a delicate sapling which will wither and die. It is the Natural Law, and Sovietization will not change it. Because of this, Public Policy demands that he whose advantages rank him among the Intellectuals shall exercise toward his less fortunate neighbor the highest type of duty; the law defines this as "uberrima fides" and imposes it upon the trustee in his relations with his cestui, the guardian toward his ward, the lawyer with his client, the teacher with his pupil, the doctor with his patient, etc., etc. Medical men as a class have always fulfilled this duty solemnly and seriously; their intimacy with the mysteries of life and death makes them a class apart; the highest sentiments of sympathy and love for helpless, suffering creatures, from the cradle to the grave, make them truly *poetic* in character and that very poetry of human relationship makes them beloved of all men who have sympathy with human suffering while it has earned for them the Rubinow-ski sneer which sees in the "Poetic Doctor" an obstructionist of those schemes of the enemies of social order who would make the practice of medicine a pawn in the game of politics for the special benefit of the "something for nothing lads." It is the poetic character of the medical man which impels a John B. Murphy, of happy memory, to forego his *rights* as an American citizen to patent and commercialize, for his own benefit, a "Murphy button" which changed the mortality record in intestinal surgery almost overnight.

Human nature has a good "forgettery." The glories of the sunlight are taken as a matter of course until a dark and dismal day gives us pause, therefore it is the solemn duty of medical men at this time to keep the public eye focused upon the poetic devotion and self-sacrifice of the doctor in peace and in war so that the public mind may be properly receptive of the warning which it is the duty of medical men to convey, that the citizenry may know the viciousness of hysterical public health legislation of this type and public opinion moulded against it; there are two things which "speak right out in meeting" when the ordinary type of legislator is legislating—Money and Votes. The propagandists of this miscalled welfare legislation have the money, but medical men have the confidence of the people which means *votes* sufficient to smash party solidarity to bits if we go to the people with the facts and ask their support regardless of party affiliations. This is not a theory of a dreamer, it is a demonstrated fact of which the Campaign of 1919-1920 furnished sufficient evidence to prompt the New York State Legislature of 1920 to send to the scrap heap 13 out of 13 bad public health bills which would have made the profession of medicine a piece-working trade and the people of the State the victims of a debased and degenerated type of politically dominated medicine.

IT WOULD BE UNCONSTITUTIONAL.

When I began, in my County, to awaken the medical men I heard, ad nauseam, "Why, Doctor, they couldn't pass such bills, they would be unconstitutional!" Poor, innocent babes! the American people said that about Prohibition and rolled over and went to sleep again, and awoke one fine morning to find that it was the *law* and the Judiciary was impotent to change the situation because, you see, the present day collective parties to the contract called the Constitution had, by their indifference and civic indolence, permitted a little group of fanatics, exhaling an odor of mock sanctity, to impress upon the Legislators of the States and the Nation that *they* were representative of American thought; the minority was organized and the majority was not, and was not even well informed: Now they must take their medicine like little men because *equity* says, "He who will not speak when he may, may not when he will." This is not a nation of drunkards, therefore prohibition affects only the pleasure of the palate and the degree of conviviality of the average American Citizen, as smoking pleasurably stimulates the olfactory nerves and conduces to comfort and contentment; Vicious public health legislation, however, will affect the health and life of the citizenry; Will the public "forgettery" help the work of the forces of unrest to prostitute the agencies of healing or is there enough of the Spirit of '76 left to produce sufficient Paul Revere's to carry, and Minute men to receive and transmit a warning to arouse the American People to a realization of the Fact that this is not the Medical Men's fight for an economic existence, but *was* the precursor and *is* an aftermath of the World War; the Forces of Unrest against the constituted agencies of Order, and False Doctrinaires, the Herr Professors, the Professional Philanthropists and the Busy-body Social Surveyors who constitute the High Priests of the congregations of "worshippers at the shrine of something else than Americanism" against the traditions and institutions of this country, for which the men and women of all generations have given their lives, were the pre-war Kulturists, the war-time pacifists and obstructionists and are the present-day university, magazine, parlor and gutter agitators who abuse the liberty of speech and of the press and are permitted to get away with it.

ORGANIZED KNOWLEDGE IS POWER.

To teach, one must know and it is the duty of medical men to acquaint themselves with the *facts* of this vicious legislative propaganda and with the anti-American attitude and affiliations of the propagandists who see in what they euphemistically label

"State Medicine" a means of accomplishing what they failed to do through Compulsory Health Insurance propaganda, because the people know more about that tricky legislation, now, than the legislators did when they voted for the Davenport-Donahue Compulsory Health Insurance Bill in the N. Y. Senate in 1919. If the propagandists can "put across" State Medicine as a wedge for the subsequent national socialization of medicine, with a Secretary in the Cabinet, and a Federal Department subrogated to the right, title, interest, control and domination (politically) of the agencies of healing, public and private, corporate and individual, then that group of radicals will be content and some professional philanthropists and social surveyors, etc., will retain their jobs and receive their pay from the coffers of some of the Foundations and others through the finance department of the organized forces of unrest.

WHAT STATE MEDICINE IS.

State Medicine always has been and always will be, until organized Government gives place to anarchy, and order is superseded by chaos. Just what *is* State Medicine? It is the practice and application of the principles of medicine by the State, as such. It is properly made manifest through the Preventive Medicine of the Departments of Health and Education and Public Works and as Curative Medicine through the Departments of Charity and Correction and Labor.

It is State Medicine for the Nation, the State, or the Municipality to maintain quarantine against epidemic disease from without or from within.

It is State Medicine to safeguard jealously the food, water, and fuel supply of the people and the sanitation of dwellings and the removal of food waste and other noxious materials from the places of habitation.

It is State Medicine to teach personal hygiene in the schools and forum and through the teacher of teachers—the public press.

It is State Medicine to provide adequate hospital, dispensary and laboratory facilities for the poor and to safeguard the insane, mentally deficient, and epileptics, whether rich or poor.

It is State Medicine to provide Research Laboratories for the study of disease and its relief and for the State to be as "poetic" as the individual Doctor in giving the results to the world.

All these things and more are State Medicine and in the practice of them the domestic privacy, self-reliance, and self-respect of the citizenry is respected and safeguarded by law and labor is not set apart as a distinct and dependent class.

To do these things requires trained medical men and women and materials scientifically dependable, and it is right that the State should provide the best possible and that the work should be made attractively remunerative so as to get the best possible results for the preservation and conservation of Public Health and the personal well-being of its citizens.

It is right and meet and just that the State should do these things generously and well and that every resource of the State should be taxed to do them; it is right that every power possessed by the Administrative, Judicial and Legislative branches of the government should be exercised to accomplish this economic perpetuation of the money and man power of the State and there is not a doctor, worthy of the name, who will not only pay his share, but lend his every effort as an individual and through his class, aye, and spend himself as no other citizen is capable of doing and no other class of citizens has done; the low death rate in this country, which is the envy of the world, is evidence of record of constructive medical citizenship.

WHAT STATE MEDICINE IS NOT.

It is not right, however, that this function of the State or nation should be prostituted to the penalization, by panelization, of the Profession of Medicine, the pauperization of the people, and the profiteering of the politician and professional philanthropist through a policy of inverted economy parading under the specious title of "Welfare" and wearing the cloak of the "Brotherhood of Man" as a Compulsory Health Insurance Act, a State Medicine Act, a National Socialization of Medicine Act, a Coercive Medical Practice (Reregistration) Act, a Drugless Therapy Act, or any group or combination of these Acts until and unless the People who are the heirs to the rights of the collective parties to the Constitution of the State and Nation are afforded a full, free, and frank exposition of the *facts* which the propagandists dare not submit and the medical men *must*, or prove false to their trust. To do this medical men must *know* and *teach* their people, in the home and on the street, in public halls, and in the lay press, by exhortation and in debate and this they can not do unless they organize as citizens in professional Guilds and Associations or by investing their scientific societies with a dual function,—the study and mastery of social as well as physical epidemic disease so that the quarantine against hysterical and vicious public health legislation may be as absolute as against the bubonic plague.

It is not right that the right of distribution of 10.3 cents of every dollar a working person in the State of New York earns should be taken from him, directly, as premiums, or indirectly, as premiums-plus-taxation (to make up the deficit), by writing Compulsory Health Insurance into the Laws of the State of New York at the behest of organizations with high sounding titles whose officer bodies are dominated by men and women in sympathy with the Rand School and the doctrines of the Third Internationale, and the Sovietization of American affairs, and out of sympathy with the traditions and institutions of our Country.

It is not right that a measure like the Sage-Machold Bill (N. Y. Senate Bill 1533), which completely changes the people's plans for the treatment of human ills should be jammed through a Legislature without giving the people an opportunity to learn and judge and decide whether they want the function of salutary *state medicine* expanded to embrace the absorption of the agencies of healing under a political State head operating through political bodies like Selectmen and Supervisors in villages and towns and small cities and such bodies as the Board of Estimate and Apportionment in large cities like New York. That bill was killed in Committee, but will be introduced next session.

It is not right that such political bodies should be vested with power to acquire the control of existing hospitals and other agencies of healing, or to erect others in competition with them in the most approved *trust* fashion of taking over or crippling the independent operator so that he must submit to *panelization* "eventually, so why not now?"

It is not right that a huge political machine, beginning with a State Superintendent of Health taking his appointment from the party in power and extending down through the health officers who take their appointment from the Boards of Selectmen, Supervisors, etc., and passing out through hospital superintendents, internes, and visiting staffs designated by medical boards which are themselves the appointees of lay political bodies, should be constructed, with the health of the individual tax-paying citizen as a pawn in the game and his right of *free choice* of who shall stand between him and death when disease enters the home actually or constructively eliminated and the Poetic Doctor of his family, in whom he has confidence, forced by economic necessity to submit to panelization as part of this gigantic scheme to subordinate the agencies of healing to the State socialization of medicine and to convert the sacred profession of medicine into a piece-working trade or groups of discontented salary workers under the domination and control, in the exercise of their medical faculties, of district foremen for whose medical opinion, in the circumstances of the case, the average self-respecting doctor of today would not give a "whoop in hades." Yet all these things are part of the provisions of the Sage-Machold Bill in its practical operation because the Judicial branch of the Government would be bound to interpret that statute according to the "ordinary meaning of words" which is far different from what the propagandists intend the average man to think they mean; let me give you a startling example:

PROPAGANDA VERSUS OPERATION.

A Medical Practice Act (Kenyon Bill, Assembly Bill 840), was introduced at Albany this year; it is known as the Medical Reregistration Act, and forms an Amendment to the already existing Medical Practice Act, Sec. 164, Chap. 49 (1909), constituting Chap. 45 of the Consolidated Laws under which Physicians now exercise their faculties. The propagandists said (and some of the prominent leaders of medicine in the State actually believed) that the purpose of the Bill was to provide a proper census of the medical forces of the State and check the illegal practice of medicine by transferring the prosecution of such cases from the district attorney of a County to the attorney general of the State: The introducer of that Bill pleaded for its passage on the ground that the State Medical Society Committee had endorsed it; another Assemblyman said it was a bad Bill, that the rank and file did not want it and it was killed. Why? We need a medical census as much as a cat needs two tails; we have one now, and the U. S. Census Bureau has about completed another; the implication that the district attorneys of the Counties in this State select the unlawful and illegal practice of medicine as the channels through which to manifest their betrayal of trust is not warranted by the facts and, even if true, would not warrant this new law because the law under which the District Attorney now exercises his function makes him a *District* Attorney in the *District* which forms part of the Attorney General's jurisdiction and the Attorney General, for cause, may supersede the District Attorney for any county in the State, and through a special Deputy Attorney General conduct any prosecution in which the State, as such, is a party in interest. Again, *why* should this Bill have been killed? Because it resurrected and revivified a part of the original Medical Practice Act which was necessary and equitable in 1896 to provide for the endorsement of diplomas and licenses of those graduating in medicine prior to 1895 (of whom there are not a half-dozen in this State today whose registration of license has not been effected or contains some technical defect which requires remedying); but at this time, a quarter of a century after that section had served its purpose as an enabling clause to permit the Regents to recognize de facto physicians as de jure in accordance with the (then) new law, this section is entitled to remain dead instead of being brought back to life by an alteration in the fee from $25 to $50 for endorsement, without examination, of the diplomas of those graduates *prior to* 1895, (possibly six out of the 15,000 Physicians in the State) and by the additional recognition of an unofficial organization, the *National Board of Examiners*, as an examining body in the process of licensing physicians. The two changes in this Section of the law and the provision for *annual* reregistration and the investiture of the licensing body with discretionary powers and the withdrawal of the moral interdiction of feticide and infanticide and contraception (Sec. 170-d), so materially alters the Medical Practice Sections of the Public Health Law as to make it operative as a legislative entity with the Status of *new law* and in considering the mandamus proceeding of a doctor, graduating *after* 1895 (who was in disfavor because he would "not help make operative the Compulsory Health Insurance Bill if passed"), to command the Reregistering Bureau to accept his two dollar fee and reregister him *without another examination*, the Judiciary of the State would be powerless to grant relief because it would be bound by the "ordinary meaning of words" in the interpretation of that Statute; this Medical Practice Act, if passed, taken with the ruling decision on the *police power of the State* in this connection (Dr. Dent vs. State of West Virginia, 129 U. S. Reports page 114, year 1889), would serve as the fulfillment of the threat of a New York Senator speaking at the meeting of the 11th Assembly District Chapter of the Professional Guild of Kings County, Oct. 31, 1919, during the fall campaign, against Compulsory Health Insurance, when he said: "If you refuse to make operative the Compulsory Health Insurance Bill, if passed, your licenses to practise medicine will be taken from you under the Police Power of the State." In the pamphlet which I had written a few months previous to this threat (The Menace of Compulsory Health Insurance), I had said the same thing in warning (paragraph 36).

"We take our license to practice medicine from the State and *what the State giveth the State may take away;* better that, a thousand times, than that

we should be a party to a plan which debases our sacred professions, endangers the Public Health, increases the death rate and the days-lost-per-year from illness of the people of this State, as it (Compulsory Health Insurance), has demonstrated its capacity to do in Germany where, for thirty-five years, it has rested as a curse upon the body politic, as part of the infamous Kultur inaugurated by Bismarck and carried to ruin by the unspeakable Paranoiac of Potsdam."

WHAT IS BEHIND THIS LEGISLATION?

The same force that exploited Compulsory Health Insurance and inspired that threat is exploiting State Medicine and inspired the other threat of a Vice-President of the American Association for Labor Legislation made at the Kings County Dental Society, Dec. 11, 1919, "If you succeed in defeating Compulsory Health Insurance *you will have to take State Medicine.*"

The same force that has exploited those two vicious types of legislation and the Medical Practice Act as a coercive measure and inspired those two threats against the ancient and honorable profession of medicine is precisely the same force which is exploiting the national socialization of medicine which aims to create a Federal Department, with a Secretary in the Cabinet, to have the same political domination and control in the Nation that there would be provided in the States under State Medicine Bills and to be subrogated to the right, title, interest, control, and domination of all the agencies of healing which such State medicine bills would insure.

The force which initiated this destructive type of legislation is made up of organizations designed to promote legislation, ostensibly for the welfare of the community, but really for the development of a Communism which takes no thought of equity; for example: at the 1920 hearing on the Davenport Compulsory Health Insurance Bill, a man, flat of foot and sharp of speech, said "The Doctors object to this Bill? what do we care? *It is our will*"; he claimed to represent a Labor organization, probably the same one which the State Industrial Commissioner referred to when, at the hearing on the same Bill in 1919, he shook his fist in the faces of the Senate Health and Judiciary Committee, the elected representatives of his employers, the People of the State of New York, and said "There are 700,000 *reasons* why you "gotta' pass the Bill." Rather Bolshevik, don't you think, in the face of the fact that the Menshevik of Labor in this State is 3,300,000 to make up the 4,000,000 workingmen who were supposed to be the natural beneficiaries of that Bill? It is very interesting to note that the official Report of that same Industrial Commission, January, 1920, revealed 600,000 *reasons* who would have been double-crossed had that Compulsory Health Insurance Bill become the law and the inverted economy of the propagandists prevailed.

Those organizations I speak of are supposed to be supported by the "dues-paying members" but derive their resources largely from the moneyed Foundations, the least of whose interest is the advantage these Associations for Legislation afford in providing, at the expense of the Taxpayers of the State, remuneratvie berths for the protégés of those Foundations and the graduates of their Schools of Sociology, Psychology and Philanthropy.

One feature of those organizations is that they are sure to work into their titles the words *American—Welfare*—or *Labor* or *Trade Union* or some combinations of these; they know American psychology and they agree with P. T. Barnum that "The American public likes to be humbugged" for, mark you, their Officer Body, Executive Council, and Administrative Council show the names of such distinguished personages as the President and men and women prominent in Church and State who lend their good American names and contribute good American dollars without thought of the old adage "tell me your company and I'll tell you what you are" and they would be shocked, I am sure, to see their names on such an Association's letter-head blended with some conspicuous characters whose affiliation with the Rand School and parlor and gutter Bolshevik publications and Negro exciting magazines warrants the use of a fine-comb before such an Association may lay claim to the title *American.* Surely the more 100 per cent Americans there are claimed by *any* organization, the less excuse exists for any anti-Americans and "Americans,-but."

I cannot conceive, nor can you, the interests of public welfare or of labor being safeguarded by a policy which limits *free choice* and utterly destroys the personal element between a sick citizen and his agency of healing, which makes him a card-indexed unit and his doctor an impersonal employee of the State under the supervision and control of a political medical foreman in charge of a gang and which sells to labor a depreciated health service and supplies at a wasteful price or binds the State to make good an annual *deficit* of $22.32 per average man or $90,000,000—for the 4,000,000 workingmen in the State. The honest study of the practical application of the provisions of the Compulsory Health Insurance Bill, the State Medicine Bill, and the National Socialization of Medicine propaganda reveals just such inverted economy, just such a waste of the money and man power of the State just at this time when the conservation of resources is so badly needed. This type of public health legislation belongs to the public to kill, and it is only through an aroused public opinion that sanity in public health legislation can replace the hysteria which has characterized it in the past several years.

WHAT STATE MEDICINE SHOULD INCLUDE.

All that State Medicine *is* should be continued and the Legislators should give serious thought to a much more generous policy. "A chain is as strong as its weakest link." It matters not how zealous or competent the visiting medical men of an institution may be; it matters not how faithful the house staff of medical men may be; it matters not how attentive the internes may be, the nurses and orderlies, in the last analysis, are the ones who must apply the "after care" during the 24-hours which constitute each day. $30 or $40 per month and "found" is hardly calculated to attract the highest type of employee, male or female. and the addition of a few extra, high-salaried welfare workers, each with a card-index cabinet and without contact or sympathy with the sick, save through a history card

attached to the file at the foot of a bed, does not improve the conditions. We reprove the small boy who has bitten off more than he can chew and is reaching out for another "hunk", but the present State Medicine is doing precisely that. The Craig Colony, for example, has not a decent *x*-ray equipment, and such advanced aid to diagnosis is of much value in locating the mechanical causes of epilepsy; the cattleization of mental defectives in the experimental stations of this State, where there is a trim social surveyor to every small group of inmates, is one of the sad results of this miscalled welfare legislation which was passed upon a propaganda that "32.5 per cent of the rejectees of the Draft Army in New York State were mental defectives"; the citizen of this State who believes that is either lacking in civic pride or incapable of recognizing a lie; it would be ludicrous, if not so sad, to contemplate the existing fact that the State Hospital Commission, which cares for the insane, while it is competent, through its examiners in lunacy, to determine between sanity and insanity is incompetent (legally) to determine between mental defection and "normalcy" which is made the function of a Commission for Mental Defectives with its own staff of psychologists, sociologists, philanthropists, psychanalysts, etc., etc., and its examiners in mental defection. It would seem that there is a beam in the eye of State Medicine that should be attended to before the State uses the lenses of these precious "uplifters" to estimate the mote in the eye of the poetic doctors of the State.

WHAT THE PEOPLE NEED.

All over this State are Public and Private hospitals and laboratories, with more or less complete equipment for advanced scientific diagnosis, such as *x*-ray, stomach analysis, blood and sputum analysis, etc., etc. It should be possible for an employee (or his employer) upon payment of a just and reasonable fee to any one of those institutions to get just the particular additional diagnostic information that his family physician might need and specify without having the citizen penalized by coming under the medical care of an assigned panel physician to whom he could be only a "case."

A doctor, to-day, may have this work done through private laboratories, to the great advantage of his own grasp of the patient's disease and to the great benefit of his patient and to the economic advantage of the State which shares in the rapid restoration of the sick to health and usefulness. This can and should be organized so that the existing agencies may be made available to the workingman and an equitable standard of fees for such service, based on the cost of material, plus overhead, plus service, plus a percentage margin for depreciation of equipment and reasonable profit, plus a reasonable super-charge to be turned over to the Municipality, part of which to be made into a Public Health Sinking Fund for the amplification of the facilities to meet changing conditions of population and to be available in time of epidemic and a part for the necessary expenses of Municipal supervision and a part to the State for administrative expense.

There are a lot of public school buildings eating their heads off at night for want of use; the Uplifters would remedy that by using them for Community "Lend a Hand" dances and they actually succeeded in having the plans for a new Public School (29) include a *shooting gallery!* Suppose the State Department of Health and the State Department of Education join hands and have them serve as channels of instruction in the simple rules of personal hygiene and disease-prevention which make for health in the community and the State as State Preventive Medicine.

When the calamity visited the City of Halifax, N. S., several years ago I recommended to the then Adjutant General of N. Y. State that he make some provision for emergency assignment of the medical forces of the large cities so that in the event of a catastrophe the medical men and women and institutions would know just what was to be done and who was to do it; we have all that in the Volunteer Fire Department where "running with the machine" is a civic pleasure as well as neighborly duty; the fire drill in schools and on ships and in factories is another phase of this community action in time of danger.

These plans for the legitimate amplification of State Medicine must not be permitted to exclude the unborn, neither must they be permitted to open the door for the dissemination of birth control propaganda. When a group of Uplifters present harrowing statistics of the mortality of pregnant women as propaganda for spending a lot of the State's money for maternity centres, and we find them in sympathy with and engineering the withdrawal of Sec. 170-d from the Public Health Law which exercises a moral and quasi-legal restraint over physicians who might be disposed to ignore the doctrine of "uberrima fides" and preach and practice feticide, infanticide and contraception it puzzles one to decide whether they have a keen sense of humor or a blunted sense of proportion, but we are warranted in believing that the Napoleonic Code should be applied strictly to this type of legislation, lest the control of childbreeding rather than the encouragement and safeguarding of childbearing should be the end result. The women of this State and Nation do not require information on the limitation of offspring but they do sadly need to be educated to the fact that conception initiates a radical change in body chemistry which should be intelligently considered and supervised and that this consideration and supervision should begin early in the pregnancy so that organic disease or functional toxic conditions may not endanger the mother and child. Let us afford expectant mothers opportunities for education along those lines and the medical profession will be happy; attempt to pauperize our people or treat the women of our people as brood-mares under an actual or constructive policy of compulsory maternity supervision and every decent medical citizen, Guild, Association, and Society will try to make such a law inoperative if you pass fifty Medical Practice Acts to "take away their licenses under the Police Power of the State."

This work in its entirety should be entrusted to practical medical scientists and not to theoretical social surveyors, paid professional philanthropists, herr professors and false doctrinaires, or to the political opportunists to whom the advantage of the people of the State count for little and the influence of these impressively titled organizations count for

much; this work should serve as an agency for public betterment and not as an employment agency for the Foundations' Schools of Sociology, Psychology, and Philanthropy. The people of this State and the legislators who represent them should make it their business to judge every piece of legislation bearing the endorsement or initial hall-mark of these professional "Uplifters" by the Napoleonic Code, "guilty until proved innocent" and the Lord knows it is the solemn duty of medical men of this State and Nation, in the light of their experience of the past several years, to educate the public mind to this attitude of suspicion of any group of people, organized or unorganized, that uses deception and trickery to put across this legislation,—like the "24-cents-per-week-per-employer-and-employee-premium" propaganda of Compulsory Health Insurance; the "Correction-of-illegal-and unlawful-practice-of-medicine"-Medical-Practice-Act propaganda; the "bring-the-boys-back-to-the-farm-by-having-a-hospital-community-health-centre" propaganda of State Medicine; or the "efficiency-izing-of-the-agencies-of-healing" propaganda of the National Socialization of Medicine.

Up to this moment it has been the medical men's fight aided by some practical business men who know inverted economy when they see it; the voting public backed us up handsomely last year, but there must be no let up in the campaign of education by the medical men, and the voting public must be kept "on its toes"; the medical man (or Society) who thinks it is "infra dig." to make common cause with his fellows in educating himself and his patients and friends to a realization of the seriousness of this menace will be false to his Order and fail in that "uberrima fides" which reason and the law impose upon him in his relations with his patients and the people of the State whom it is his duty to serve. A stilted Code of Ethics is a curse.

405 UNION STREET.

RECENT PROGRESS IN KIDNEY AND URETERAL SURGERY.*

BY DANIEL N. EISENDRATH, A.B., M.D.,
CHICAGO, ILL.

ONLY those who have kept pace with the improvements in diagnostic and therapeutic methods employed in Urology can appreciate the vast changes which have taken place during the past ten years. Progress has been along three lines chiefly: (1) In diagnostic methods; (2) in operative technic and the application of nonoperative methods of treatment, and (3) in the more accurate interpretation of certain familiar clinical symptoms such as ureteral colic, pyuria and hematuria.

1. *Improvements in Diagnostic Methods.*—These have been chiefly the result of the perfection of radiography as applied to the urinary tract, the chemistry of the blood as it interests the urologist and the bacteriologic study of renal infections. Let us discuss these briefly in the order named.

(a) Pyelography and Ureterography. Voelcker was the first to show that certain solutions which give a radiographic shadow, will, when injected into the bladder, ureter, and kidney, yield valuable information in regard to changes in the lumen of these structures. Collargol, first employed by injecting it with a syringe into the renal pelvis, was soon discarded because it was found[1] that if too much force was used the substance passed into

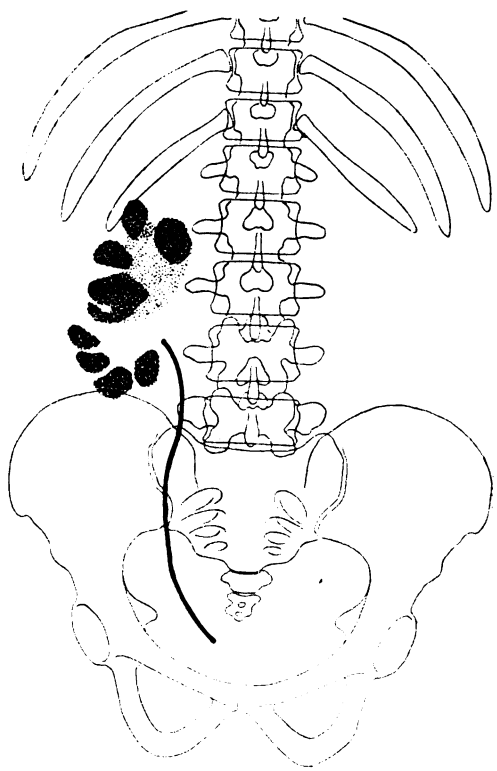

FIG. 2.—Tracing of pyelogram from one of author's cases showing the widely scattered shadows so typical of a pyonephrosis.

*Read at the March 31, 1920, meeting of the Chicago Medical Society, and illustrated by a number of lantern slides.

the systemic circulation and caused death and even if little force was used the drug was rapidly absorbed from the renal pelvis, giving rise to a dangerous and often fatal toxemia. Thorium has been quite generally employed as a substitute, but

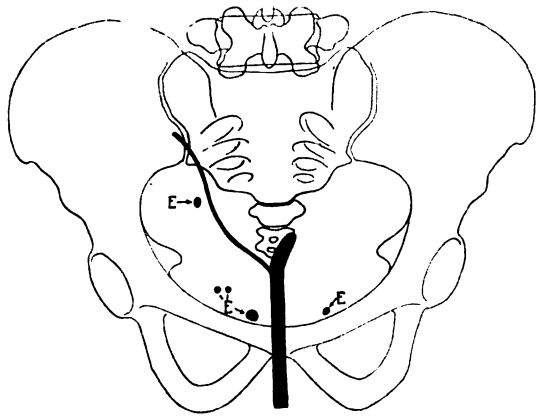

FIG. 3.—Tracing of radiograph of same case shown in Fig. 4 after use of opaque catheter. The calculus was delivered by non-operative methods and one only sees extraureteral shadows (E).

the work of Magoun[3] has shown that this pyelographic medium is rapidly absorbed and may prove fatal as in a recent case reported by Weld.[3] As a result of this experience, we have adopted a 20 per cent. solution of sodium bromide as the least toxic medium for pyelography and allow it to flow through the ureteral catheter by gravity pressure.

The pyelogram of a normal kidney shows in addition to the ampullary portion three major calyces, namely: superior, middle, and inferior, from each of which arise a number of minor calyces.

Variations from the normal pyelogram are not difficult to distinguish so that pyelography is of the greatest assistance in the diagnosis of a number of surgical affections of the kidney. The increase in size of the shadow with widening of the narrow portions of the major calyces and a club-like dilatation of the minor calyces enables us to recognize the presence of an inflammatory or

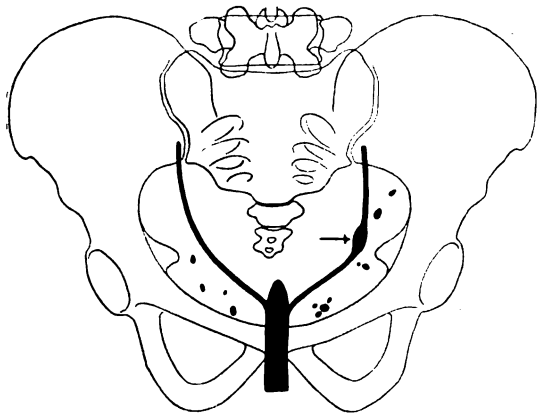

FIG. 4.—*X*-ray tracing of one of author's cases after introduction of argentide into ureter. Note nodular dilatation at location of the intraureteral shadow seen in Fig. 7.

mechanical dilatation (hydronephrosis) of the renal pelvis (Fig. 1).

In renal tuberculosis the eroded appearance of the calyces or the presence of widely scattered shadows (Fig. 2) is very characteristic.

It will be impossible for us to take up in detail the various diseases whose recognition has been rendered a far easier task than before pyelography was employed as a more or less routine diagnostic measure.

Ureterography, the opaque catheter and the employment of stereoscopic x-ray exposures have enabled us to diminish the percentage of error in the differentiation of true (intraureteral) from false (extraureteral) shadows. In a recent article[4] I have called attention to the necessity of the application of all of these methods as a more or less routine procedure.

In quite a number of cases presenting the clinical picture of ureteral calculi, the presence of multiple shadows along the course of the ureter greatly complicates matters. In some of these puzzling cases the opaque catheter alone, with or

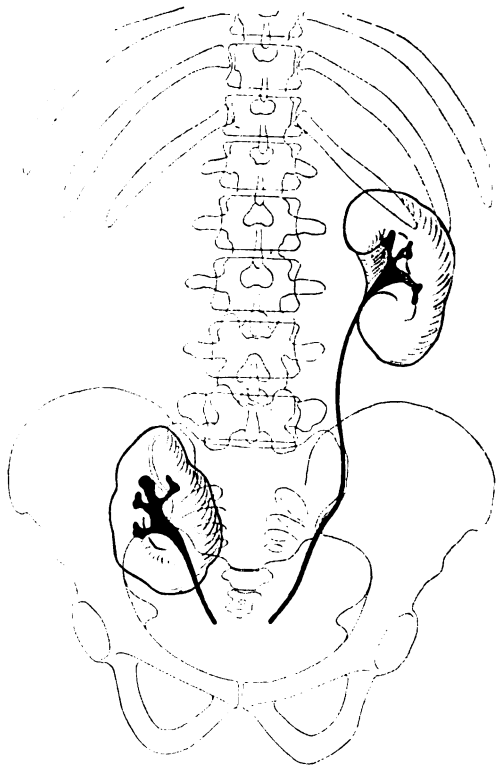

FIG. 5.—On right side the pyelogram is shown as it would be obtained in a case of ectopic (pelvic) kidney. On left side, kidney is normally located and shows a normal pyelogram.

without stereoscopic plates, enables us to decide which shadow is due to a calculus and which other shadow or shadows (Fig. 3) are due to the various conditions (phleboliths, calcareous lymph glands, etc.) giving rise to extraureteral shadows. In other cases it is necessary to employ ureterography which will reveal either a nodular dilatation at the site of the calculus (Fig. 4) or a uniform dilatation of the ureter above the point of obstruction.

In the recognition of the various congenital anomalies of the kidney and ureter, pyelography, and ureterography have rendered service of the greatest value. The condition known as congenital dystopia of the kidney, which represents a persistence of the original embryonic position of the kidney in the true pelvis, the presence of the pyelographic shadow in the pelvis proper or in

the iliac fossa (Fig. 5) causes one to suspect at once the existence of such a congenital malposition of the kidney. At times it is of the utmost importance for us to know whether we are confronted with the conditions known as horseshoe, fused, or solitary or double kidneys. The same is true of the presence either as an acquired or a congenital condition, of both kidneys on one side. Here again pelvography and ureterography enable us to recognize these anomalies before operation and to plan our operative procedure accordingly.

(b) Radiography alone without the aid of the opaque catheter, stereoscopy, pyelography, and ureterography enables us to tell with a fair degree of accuracy the exact location of calculi in the kidney, *i.e.* whether in the pelvis proper, in one of the calyces, or in the parenchyma. In cases giving the typical history of calculus in the upper urinary tract it is often possible to intensify a weak or doubtful shadow by the application of the principles underlying pyelography and ureterography, *i.e.* taking a second picture after impregnating the calculus (through the ureteral catheter) with a solution giving an x-ray shadow.

The differentiation of true intrarenal from false extrarenal shadows, such as calcified glands, gallstones, etc., has been rendered far easier through the introduction of the opaque catheter and the use of pyelography. It is estimated that in from 10 to 15 per cent. of cases of calculi in the kidney there is a recurrence of the calculi after operation. We have no definite information as yet, of the causes of such a recurrence, but renal fluoroscopy as recently proposed by Braasch and Carman[6] will prevent at least a recurrence due to an overlooked calculus.

In renal tuberculosis, radiography alone is of great service in diagnosis when it is impossible or undesirable to catheterize the ureters. The recent observations of Braasch,[6] Colston and Waters[7] have shown that one can readily recognize the more advanced cases of renal tuberculosis by the appearance of the kidney on the x-ray plate.

2. *Improvements in Operative Technique and in the Application of Nonoperative Methods.*—Of chief interest are (a) the study of the anomalies of the renal vessels and (b) the almost general substitution of the operation known as pyelotomy for that of nephrotomy.

The presence of accessory arteries and veins passing directly from the aorta, vena cava, or iliac vessels to the upper or lower poles of the kidneys compels the operator to expose these poles carefully in order to avoid serious bleeding during or after operation on the kidney.

Nephrotomy for the removal of calculi is followed in a fairly large percentage of cases by secondary hemorrhage, hence it is being used less frequently from year to year. The route of election is through an incision in the posterior surface of the renal veins where the danger of bleeding is reduced to a minimum.

The treatment of infections of the kidney involving chiefly the pelvis has been greatly simplified as the result of the direct applications of antiseptics to the renal pelvis when injected through the ureteral catheter. This method, known as pelvic lavage, enables us to cure many a severe case of pyelitis which formerly proved resistant to ordinary treatment. In the study of the bacteriology of the upper urinary tract smears made from sediment obtained after the use of the high power centrifuge have almost completely supplanted cultures or animal inoculation.

The nonoperative delivery of ureteral calculi (Fig. 3) enables us[4] in many cases to avoid operative interference and is a method which should be given a fair trial before operation is decided upon.

3. *More Accurate Interpretation of Certain Familiar Clinical Symptoms.*—I refer particularly to the well known symptoms hematuria, pyuria, and ureteral colics. Inasmuch as this forms the subject of a paper to be published in the near future, I shall only call attention to the fact that none of these can any longer be considered as pathognomonic of any particular condition of the kidney.

Only a thorough urologic study of every case will enable us to make a diagnosis and to avoid pitfalls which lie more frequently in our path in the surgery of the upper urinary tract than that of any other region of the body.

30 NORTH MICHIGAN AVENUE.

THE INDIVIDUAL FACTOR IN DISEASE *

BY F. M. POTTENGER, A.M., M.D., LL.D., F.A.C.P.,
MONROVIA, CAL.

IN the interpretation and evaluation of symptoms the patient must not only be considered as a human being, but as an individual. His own peculiar physiological balance or imbalance underlies and modifies his symptoms. While some individuals are in a state of physiological equilibrium prior to the time that they become afflicted with a given disease, many more are in a state of imbalance to start with. The symptoms of disease manifested in organs which previously were in a state of physiological equilibrium may be very different from those shown in organs in which the equilibrium was previously disturbed.

The symptom-complex of a given disease is not a result of a single factor working in a simple direct manner but a resultant of many factors working extremely complexly. The actions of different parts of the body are correlated through the nervous and endocrine systems in such a manner that no impulse can act in one tissue alone; and the higher we

*Read by title at the twenty-first annual meeting of the American Therapeutic Society, held in Philadelphia May 7 and 8, 1920.

ascend in the scale of development the more perfect is this integration of action. My meaning will be made clear by analyzing the forces which operate to produce symptoms in one of the infectious diseases. From the point of localization toxins are given off, which, circulating in the blood stream, irritate nerve cells both of the higher and lower centers. Peripherally, the sympathetic nerves are most markedly stimulated by toxins and these tend to produce the action in tissues which is peculiar to sympathetic stimulation. The sympathetic nerves in turn stimulate certain endocrine glands, particularly the adrenals and thyroid and to a less extent the pituitary. These glands are stimulated to the formation of hormones in amounts greater than normal, and these again affect nerves and other endocrine glands activating some and inhibiting others. Again the hormones may affect the higher psychical centers and there start other chains of stimuli working. At the same time that these general factors are acting, in those diseases which are localized in some particular organ such as appendicitis, gall bladder infection and pulmonary inflammations, the nerve endings in the particular organ are stimulated and reflex action is produced in other tissues, some of which is in harmony with the stimulation already effected by the processes started in motion by the toxins as described above; and some of which is in opposition.

In the final analysis, body cells have but few functions, such as motor, secretory, sensory, and trophic. These functions are normally presided over by and dependent upon nerve cells, and chemical substances which are secreted by the tissues. Whether these chemical substances, which have been designated internal secretions, act independently of or through the nerve cells is not definitely known. But the close relationship must be evident from the fact that at least most secretory, sensory, and trophic properties of cells are positively under nerve control; and the only manner in which these properties of body cells are disturbed is by nerve impulse or hormone stimulation. Motor, secretory, sensory, and trophic changes in body cells, if sufficiently pronounced to be recognized, constitute symptoms of disease. While the changes in the body cells themselves constitute the pathological anatomy of the disease, the changes in their function constitute the pathological physiology, and make up the syndromes met clinically.

Based on these physiological facts we assert that symptoms of disease are produced through either the nerves or the internal secretions. Stimuli which affect function through the nervous system and the endocrine glands may originate either in the physical or psychical systems.

We have now proceeded to the point where we can see that a theoretically, physiologically perfect man must have an anatomically perfect physical body and physiologically balanced nervous, endocrine and psychical systems; and that imperfection of a disturbed equilibrium in one of these systems will disturb the equilibrium of the others. Clinically, such perfect organisms are not recognized. All people have disturbances in physiologic equilibrium in some portion of the body when they are in their usual state of health. If this departure from the normal is marked it may stamp the individual.

Most symptoms of disease are expressed in the so-called involuntary or vegetative structures, those which are not presided over by the will. These are innervated by the vegetative nerves of which there are two divisions, the sympathetic and parasympathetic. When these two divisions innervate the same organ, one activates and the other inhibits action. In other structures action and inhibition of action are presided over by the same division of nerves. In certain individuals there is a departure from the normal in the tonicity maintained in the tissues through these nerves. Sometimes the influence is preponderantly strong through the sympathetics at other times through the parasympathetics. This conception we owe to Eppinger and Hess who have called the former sympathicotonics and the latter vagotonics. In some individuals the tonus is increased widely in practically all tissues supplied by one or the other division; in others it affects only a few organs or systems. Thus a general vagotonia may be present which consists of many of the following symptoms: Contraction of the pupil; widening of the eye slits; increased lacrymation; increased secretion of the nasal, oral and pharyngeal mucous glands, conditions commonly known as catarrh; increased salivary secretion; contraction of the laryngeal muscles such as is met in laryngospasm; increased bronchial secretion such as is met in bronchitis; spasm of the bronchial musculature as found in asthma; hypermotility and hypersecretion of the gastric glands including that of hydrochloric acid; hypersecretion and hypermotility of the intestine, leading to colicky pains and states of either spastic constipation and stasis or diarrhea, depending much on the degree of stimulation and whether the circular or longitudinal muscles are the recipients of the increased stimulation; irritable bladder; incontinence of urine and feces; lymphocytosis and eosinophilia. Sweating is also found in conditions which are accompanied by the above group of symptoms, as well as those belonging to the sympathetic syndromes. A localized vagotonia might express itself in some such syndromes as spasm of accommodation; laryngismus, hay fever, asthma, bradycardia, hyperchlorhydria, or mucous colitis. Sympathicotonia on the other hand would be represented by widespread symptoms such as the following: Dilatation of the pupil; protruson of the eye ball; lessened lacyrmal secretion; lessened salivary secretion; lessened mucous secretion in the nose and throat; lessened secretion in the gastrointestinal tract, showing particularly as a hypochlorhydria and retarded digestion; lessened motility in the gastrointestinal tract, showing as a slowness in emptying of the stomach, contraction of the sphincters of the gut, and a general relaxation of the intestinal musculature leading to the common type of constipation found in the acute infectious diseases; rapid pulse and at times high blood pressure, although vasoconstriction in one area is usually accompanied by compensatory vasodilatation in others; increase in body temperature due to (1) vasoconstriction in the superficial vessels which interferes with the elimination of heat, and (2) an increased production of heat resulting from the increased chemical action; diminution in the amount of urine; alimentary glycosuria; contraction of the ureter; contraction of the uterus;

goose flesh; increased sweating and neutrophilic leucocytosis. Increased adrenal and thyroid secretion also follow sympathetic stimulation; and this in turn produces symptoms varying in degree according to the amount of extra secretion formed. A localized sympathicotonia might be represented by such symptoms as rapid heart, lessened blood supply to a part, an increased blood pressure, pylorospasm, a localized sweating, or goose flesh.

Sympathicotonics and vagotonics react to certain diseases very differently; and, differently from those who are in a state of equilibrium so far as their vegetative nervous system is concerned. In vagotonics, parasympathetic syndromes are precipitated very easily, and in sympathicotonics sympathetic syndromes equally easily.

What is true of the vegetative nerves is also true of the endocrine glands. Hypo and hyper function on their part is very common; and these states cause a reaction different from that in the normal.

A third physiological factor in the production of variability of symptoms is the higher or psychical centers. Man adapts his physical being to his surroundings through his sensory and motor nerves. Sensations which affect the physical man may alsc affect his psychic centers. According to the manner in which the psychic being is able to adapt itself to its physical and social environment will the psychic equilibrium vary. When the psychic state is in a condition of imbalance this is reflected through both its nervous and endocrine systems. Therefore, we find primarily both a physical and psychical basis for variability of stimulation of the nervous and endocrine systems, which in turn govern and produce the common disturbances in physiological action which make up the syndromes of disease.

We must accept, as a basis for studying symptoms, not only the normal nervous, endocrine, and psychic reactions, but the departures in these reactions peculiar to the patient under investigation; for clinical syndromes will vary as these factors vary. Thus syndromes of the same disease will vary not only in different patients; but in the same patient at different times.

A patient with a disease of the gall-bladder or appendix is prone to have more symptoms on the part of the stomach and intestines if he is of a vagotonic disposition than if of a sympathicotonic. During the acute attacks he is more prone to nausea and vomiting; and during the chronic state, suffers more from hyperchlorhydria and spastic constipation. In chronic pulmonary tuberculosis the vagotonic has a slower pulse, suffers more from nausea, vomiting, hyperchlorhydria, colicky pains, and spastic constipation than the sympathicotonic. The vagotonic tuberculosis patient also often suffers from an asthmatic type of breathing and is prone to nasal and pharyngeal catarrh.

Pregnancy and the menopause offer excellent examples of the difference in re-activity according to: (1) the irritability of the vegetative nerves; (2) the activity of the ovarian secretion; and (3) the psychic state. The ovarian secretion expresses its action preponderantly upon the sympathetic division of nerves. This influence is felt throughout the menstrual life of woman and is exaggerated during the latter half of the menstrual cycle. If this secretion is withdrawn, as it is during pregnancy and the menopause, whether naturally or artifically produced, the sympathetic nerves have a stimulus removed from them to which they have become accustomed. If the patient should be normally strongly sympathicotonic, the withdrawal might still be insufficient to disturb the equilibrium of the vegetative system; on the other hand if she should be strongly vagotonic, the withdrawal of the sympathicotropic ovarian secretion would allow the hyperirritable parasympathetics to act with a lessened opposition and the symptoms would be correspondingly severe.

Again, the manner in which a woman adjusts herself to pregnancy or to the menopause depends much upon whether she is strongly hyperovaria or hypoovaria. The patient who is hypoovaria does not miss the withdrawal of the secretion so much, consequently passes through the early weeks of pregnancy with little discomfort while she who is hyperovaria suffers the loss of a strong stimulus to which she can not readily adjust herself. The worst difficulty of adjustment is met in the patient who is strongly vagotonic and at the same time markedly hpyerovaria.

Pregnancy and menopause are often accompanied by serious psychic imbalance and this again reacts upon the vegetative nerves and the endocrine glands and causes most complex reactions. The psychic equilibrium depends much upon the manner in which the patient stands the withdrawal of the ovarian secretion; therefore, it is apt to be most markedly disturbed in the hyperovaria, vagotonic woman in whom it often assumes a complete mental unbalance.

VIVIDIFFUSION WITH INTESTINAL MEMBRANES.*

By G. R. LOVE, B.S.,

CHICAGO, ILL.

DURING a recent study of some of the substances constituting normal blood it was necessary to employ vividiffusion tubes which were permeable to dissolved colloids. A method was therefore devised whereby intestinal membranes could be prepared for such purpose. The intestinal tubes present such distinct advantages over collodion tubes that we have virtually discarded the latter. The collodion tubes present a very practical disadvantage; namely, if the tubes are made firm and compact they are also brittle, if they are soft and pliable they are also delicate. With the intestinal membranes these difficulties are largely overcome.

The intestines of the cat, rabbit, turkey, and chicken have been employed. However, since the chicken intestines were the most available most of the work was done with them.

Preparation of Chicken Intestines for Vividiffusion Tubes.—The fresh small intestines are used; they may, however, be preserved for a time in 0.1 per cent. $HgCl_2$. The intestines must not be loaded with fat at the peritoneal reflection. The mesentery is cut away 5 to 10 mm. from its reflection on the intestine. The intestines are then cut into 12 to 24 in. lengths and the contents are washed out. The intestines are now turned inside out upon a

*From the Department of Chemistry, Hahnemann Medical College of Chicago.

glass rod or tube. The mucous membrane is removed in a manner similar to peeling a banana. The process is started at one end of the intestine by cutting transversely through the mucosa to the submucosa and gently massaging the incision. The intestines are now re-inverted and removed from the glass rods.

A solution of albumin is heated to boiling and cooled. The intestines are soaked in this suspension for 6 hours or more. They are then fitted on glass rods whose diameters are about two-thirds the diameter of the intestines. Each rod with its enveloping intestine is suspended in a saturated solution of NaCl previously heated to 80° C. The intestine will contract to two-thirds to half of its original length almost instantly. After it has ceased contracting it is placed in a NaCl solution at room temperature for about an hour. The intestines are now removed from the rods and are cut into the desired lengths for vividiffusion tubes.

The purpose of the precipitated albumin is to fill up the capillaries and other small vessels. The rods serve as moulds upon which the intestines are shaped when they contract. The tubes prepared in this manner are strong and very elastic. Sometimes a tube is too elastic. This is reduced by soaking the tube from 20 seconds to an hour in half saturated tannic acid. In assembling the vividiffusion apparatus the tube on the arterial side should be slightly less elastic than the venous tube, because the arterial tube will have a higher internal pressure. The external pressure is maintained just below the systolic blood pressure, so that with each heart beat the tubes will be forced to expand with the systolic wave—and will contract automatically during the diasystole. In fact the heart beats are most distinct when the internal and external pressures are approximately the same.

Hemoglobin and many other colloids will diffuse through these tubes. However, if one does not desire molecules of such size to diffuse, the tubes can be so treated that the diffusion of such substances as hemoglobin is practically stopped. There are several processes for doing this. First, the albumin — NaCl treatment may be repeated; second, the tubes may be soaked in albumin for several hours and then placed in saturated picric acid for 15 minutes; third, the tubes may be filled with oxalated or citrated blood and then suspended in 5 per cent $CaCl_2$ until the blood is full clotted. The tubes are occasionally injured when they are removed from the glass rods and it is advisable to test each tube before attaching it to the diffusion apparatus. This may be done by filling the tube with laked blood and suspending it in clear water. The same precautions are taken to prevent coagulation as are taken with the collodion tubes.

The advantages of the intestinal tubes over the collodion tubes may be summarized as follows:

1. The intestinal tubes are stronger and are less liable to become injured.

2. They are elastic and are therefore more practically suited to vivicirculation.

3. They can be so prepared as to be permeable not only to crystalloids, but also to colloids such as hemoglobin, albumin, toxins, and fibrinogen.

Assistance received from Dr. J. C. Blake in the prosecution of this work is gratefully acknowledged.

Medicolegal Notes.

Bequests to Hospitals.—A corporation was organized in California in 1862 under the provisions of the act of April 22, 1850, for the purpose of securing to its members without payment, otherwise than of dues, medical and surgical treatment. It established a hospital and employed physicians. The articles of incorporation provided "that the object of said society should be mutual assistance of the members thereof in case of sickness." It is held that the corporation was not a "charitable or benevolent society" within the meaning of California Civ. Code, Section 1313, providing that no property shall be bequeathed or devised to such a society or corporation in trust for charitable uses except the same be done by will duly executed at least thirty days before the testator's decease, although persons not members could be admitted to the hospital on payment of such sum as the directors should exact, and although any white person of good health could be admitted into the society on payment of dues. One of the essential features of a charitable use is that it shall be for the public benefit, either for the entire public or for some particular class of persons, indefinite in number, who constitute a part of the public.—*In re* Doll's Estate, California Supreme Court, 187 Pac. 428.

Requirements of Proof in Hernia Cases.—Claims for compensation under the Colorado Workmen's Compensation statute of 1915, based upon hernia, are governed by the special provision in section 52 as follows: "A workman in order to be entitled to compensation for hernia must clearly prove: (1) That the hernia is of recent origin, (2) that its appearance was accompanied by pain, (3) that it was immediately preceded by some accidental strain suffered in the course of the employment, and (4) that it did not exist prior to the date of the alleged injury." In a claim that claimant "suffered an accidental strain which resulted in an inguinal hernia," the claimant testified, on the first point, that in 1909 he had a double hernia; that he could not tell how it occurred; that he suffered no pain; that it came upon him while he was engaged in the lightest kind of work; that he lost no work as a result of it; that he was operated on and thereafter wore a truss. It was held that with this very unsatisfactory evidence before the commission it was impossible to say that the "recent origin" of the hernia was clearly proven. It was also held the claim was not sustained on the other three points by the evidence. Judgment confirming an award was therefore reversed.—McPhee, etc., Co. v. Commission, Colorado Supreme Court, 185 Pac. 268.

Accident and Sickness Insurance; "Confinement Within the House."—The St. Louis Court of Appeals, Missouri, holds that a nurse who became afflicted with subacute congestion of the conjunctiva, accompanied by iritic irritation and eczema of the eyes and eyelids, calling for exclusion of light from the eyes and exercise in the open and fresh air, was not "totally disabled and confined within the house," within the meaning of that phrase in an accident and sickness policy, where she called for several weeks at her physician's office for treatment, and by his advice went from place to place for change of air and treatment.—Bucher v. Great Eastern Casualty Co. (Mo.) 215 S. W. 494.

Ratification by Corporation of Its Agent's Unauthorized Employment of Physician.—In a physician's action for medical services to an employee of the defendant corporation at the request of the defendant's general manager, who was specially authorized by the corporation to employ first aid medical assistance in case of injury to the employees, received while performing their duties, but not to employ physicians generally, the evidence tended to show that the corporation was informed of the fact that the plaintiff was rendering services beyond first aid and remained silent. Under these circumstances, it was held that the question of ratification should have been submitted to the jury, and that it was error to peremptorily instruct the jury to return a verdict for first aid only, since it is a well-established rule that an employer may ratify the unauthorized acts of his agent by silence and acquiescence.—Baker v. Brown & Hackney, Arkansas Supreme Court, 215 S. W. 578.

THE PATHOGENESIS OF TRAUMATIC LESION OF THE ORBIT DURING DELIVERY.

AMONG the numerous ocular lesions which have recently been experimentally produced with the basiotribe by Lévy of the Baudelocque Clinic, at Paris, two types of lesions which are almost invariably produced are dislocation of the eye without fracture, and fracture without exophthalmia. To explain the lesions an attempt was made to ascertain what kind of compression was required for each lesion and the mechanism of the lesions.

In a first series of experiments unprepared fetal heads were used, and after compressing them in their various axes they were dissected. Occipito-frontal applications of the instrument were not studied, because in these cases the lesions obtained are the result of a well-known cause, namely, the direct action of the traumatic agent on the ocular globe. But on the other hand, lesions caused by indirect pressure were found to be of the greatest interest. In order to be produced, these orbital lesions having an indirect cause required that the application of the force should be over the petrous region on one side and over the mastoid region on the opposite, or farther forward over the parieto-malar region. In other words the application of the instrument was petro-mastoid or petro-parieto-mastoid. When the application was almost symmetrical with moderate and continued compression, the orbital roof gave way quickly, the fracture occurring the so-called papyraceous area without resulting in exophthalmos. In oblique applications with the same amount of compression an exophthalmia was produced but no fracture. However, in sudden violent crushing it was noted that no matter what the application was the result was invariably a fracture of the orbital vault, but always with integrity of the optic canal and usually of the optic nerve.

In a second series of experiments the mechanism of the production of the lesions was studied. By removing the contents of the orbital and cranial cavities the changes produced in the long walls by compression could be directly demonstrated. In oblique applications—ptero-mastoid—a narrowing of the orbital cavity from the fundus towards the exterior took place. By compression, the bony triangle, thanks to the depressibility of the pterion, moved forward towards the greater extremity of the sphenoidal fissure, causing it to progressively disappear. Therefore, it was possible to conclude that there was compression of the ophthalmic veins passing through the highest portion of the sphenoidal fissure resulting in circulatory disturbances in the vascular system composing the ophthalmic veins. As to the vault of the orbit, it remained intact as long as the pressure made by the basiotribe was progressive and moderate. This compression of the ophthalmic veins could be made very manifest by resorting to an ingenious device consisting in replacing the ophthalmic veins in the sphenoidal fissure by a metal wire covered with an even layer of modeling wax, forming a stem having a diameter such that it could be passed freely into the sphenoidal fissure when no compression was being made on the fetal skull. If while this was being compressed, an attempt was made to withdraw the stem it came away without any wax remaining on the portion which, during the maneuver, had been successively brought in contact with the bony ring. On the contrary, the stem should have only a slight circular depression corresponding to the point of contact with the bony ring if withdrawn from the sphenoidal fissure after the basiotribe had been removed. Therefore, in oblique applications a flattening of the sphenoidal fissure was produced, with strangulation of the structures contained within it. In symmetrical applications during compression the rigid and immovable orbital wings undergo no inflexion, but the very thin orbital vault curves towards the cranial cavity and then fractures, always giving way in the papyraceous area.

From these experiments it becomes evident that both exorbitism and fracture of the orbital vault result from compression of the pteric area and that the type of lesion is the consequence of two factors, namely, the direction of the compressing force and the suddenness of the traumatism. Any sudden trauma generally produces fracture of the orbital vault no matter what may be the direction in which the fetal head is seized in the instrument, but in any progressive moderate pressure the type of the lesion depends upon the grip taken on the head: in symmetrical grips there is fracture of the orbital vault without exophthalmos, in oblique grips the inverse is true.

These data explain the mechanism of exorbitism, which is the consequence of strangulation of the ophthalmic veins from narrowing of the sphenoidal fissure. However, experimental exorbitism obtained on the cadaver is never very marked because the veins are collapsed. In the living subject this strangulation of the ophthalmic veins another factor becomes added, namely, the increase of the blood-pressure in the vascular territory comprising the ophthalmic veins. Therefore it would seem logical to admit—and this is confirmed by clinical observation—that the vessels rupture and create hematomata which, when retro-ocular may continue to increase after removal of the traumatic agent, and consequently increase the degree of exophthalmia to such an extent that the globe may be dislo-

cated forward and may even be forced out of the orbit in some cases, as has been observed.

The increase of the blood-pressure and rupture of the small vessels forming the ophthalmic veins, may likewise explain other traumata having an indirct cause, such as blood suffusions of the conjunctiva and hemorrhage in the anterior chamber, or retinal hemorrhage and glaucoma. As Lequeux has pointed out, the hemorrhages occur all the more readily when some pathologic process has changed the vascular walls, and in this respect one should recall the peculiar predisposition of premature infants who are particularly sensitive to obstetrical traumata of all kinds.

FACIAL PARALYSIS AND WEBER'S SYNDROME.

IN cases which have come to autopsy lesions localized in the cerebral peduncles or involving them have been found, such as hemorrhage, softening, tumors (tuberculomata, gliomata, syphilomata), or traumatic lesions of the base of the skull, but the latter have not been clearly made out. The symptomatology is likewise complex and lesions may exist in a peduncle that are only found at autopsy. Therefore, very precise conditions must exist in order that Weber's syndrome shall be realized. The fibers of origin of the common oculomotor, the pyramidal, and geniculate fasciculi are proximate to each other in the peduncle and consequently may be involved by the same lesion, and if the latter is limited to the pyramidal fasciculus there will be a hemiplegia on the opposite side, since the fibers involved are those which traverse the neck of the bulb for the innervation of the muscles on the other half of the body.

A lesion located at any point whatever on the track of this fasciculus—cerebral cortex, internal capsule, peduncle, protuberance, pyramids of the bulb—that is situated above the point of decussation, will invariably produce a hemiplegia on the opposite side. If the lesion involves the geniculate fasciculus new symptoms will arise. This fasciculus carries the stimulus from the cerebral cortex to the nuclei of origin of the cranial motor nerves — facial and hypoglossus — and the fibers of this fasciculus, entering into the nuclei of these two nerves and after intersecting those of the opposite side, will make their action felt in the muscles of the opposite side. As symptom of the lesion there will be a generalization of the hemiplegia over the entire opposite side including the face and corresponding half of the tongue.

Suppose the lesion involving the pyramidal fasciculus and the fibers belonging to the facial is seated below the intersection of the geniculate fasciculi. At this point the fibers of the facial go directly to the corresponding side of the face; therefore the paralysis on the sphere of the facial will be on the same side as the lesion, and since intersection of the pyramidal fasciculus has not as yet taken place the limbs on the opposite side will be paralyzed or the Millard-Gubber syndrome will be present. The characters of the latter are sufficiently distinct for localizing the lesion in the bulboprotuberential region. On account of the connection between the nuclei of the facial and external oculomotor, there may be a paralysis of the right externus on the same side as the facial, so that all these symptoms differentiate the two syndromes from each other and exactly indicate the part played by the lesions present.

Now, how is Weber's syndrome realized? Whether the lesion of the peduncle at the same time involves the fasciculi of the foot only and the fibers of origin of the common oculomotor, a paralysis of the latter nerve on the same side as the peduncular lesion ensues. In some cases where the damage is extensive, Reil's band may be involved so that disturbances of sensibility became added to those of motility. When the peduncle is totally destroyed the facial will be involved. The arrangement of the nuclei of the common oculomotor explain why in some cases ophthalmoplegia of the third pair is complete, while in others it is simply external or internal or even limited to a single muscle. These nuclei in close proximity, but nevertheless quite independent of each other, give off their own fibers and an insulated lesion of the latter gives rise to isolated paralyses in the sphere of the third pair.

The pupil shows no change but accommodation is disturbed. Conjugate deviation of the eyes and face occurs when the lesion extends to the optic strata. Peduncular hemiplegia has nothing characteristic and Bidon has published three cases of hemichorea due to tumors of the cerebral peduncle. When the lesions of the pyramidal fasciculus are deeply seated, symptoms of permanent contracture appear, due to degeneration of the pyramidal fasciculus and bulbar pyramid. Ataxia is due to involvement of the upper floor of the peduncle, the superior cerebellar peduncle for example.

D'Astros supposes that disturbances of speech are due to a lesion of the geniculate fasciculus which carries the stimulus from the cortex to the facial and hypoglossus and a so-called fasciculus of aphonia has even been described in the foot of the peduncle. But aphonia must not be confounded with difficulty of speech, which is usually due to lesions of the Sylvian artery. The hemiopia mentioned by Joffray in his case was supposed to result from a clot in the posterior cerebral artery which hindered the circulation in the occipital lobe, and in this case Weber's syndrome was only temporary.

Vasomotor disturbances—edema of the paralyzed limbs in Mayor's case — have been encountered when the lesions were extensive, so that a vasomotor localization cannot be suspected to exist in the peduncles. On the other hand, the thermic disturbances can be accounted for, because Ludwig, Thiry, and Schiff place the vasomotor centers in the protuberance and the cerebral peduncles. With all these diagnostic elements at our disposal the symptoms can be unravelled and the presence of Weber's syndrome detected. This having been admitted upon a sure basis, the diagnosis of a lesion of the cerebral peduncle will be made.

THE DIAGNOSIS AND PROGNOSIS OF THE INFECTIOUS ERYTHEMATA OF TYPHOID FEVER.

THE diagnosis of the erythemata arising during the evolution of typhoid fever is usually an easy matter when due to some mechanical cause or from the ingestion of certain drugs. But it is another matter when a diagnosis is to be made between a drug eruption and an infectious erythema. The erythemata of typhoid fever may be mistaken for measles or scarlatina—particularly in children—especially if the symptoms belonging to these diseases are not well marked. However, the evolution of the eruption differs in typhoid from the others, while the absence of a catarrhal process in the ocular, nasal, and laryngeal mucosæ will eliminate measles. The diagnosis of scarlatina might be made especially on acccount of the high temperature, the presence of an angina, and the peculiar evolution of the eruption. The rash met with at the onset of typhoid when the affection is not fully declared, may by its aspect, color, and short duration simulate the rash observed at the period of invasion of variola. But in this disease the erythema is more prone to develop in the inguinal region and upper part of the thighs and is usually preceded by vomiting, lumbar pain, and constipation. Finally, the gravity of the symptoms which accompany the malignant forms of infectious erythemata may, in some cases, lead the practitioner to suspect typhus fever. The principal elements of differential diagnosis will be the essentially epidemic and contagious nature of the latter disease, its sudden invasion, the predominance of nervous phenomena and lastly the peculiar characters of the eruption appearing from the third to the fifth day on the abdomen, flat pink spots or papules, isolated or confluent, soon becoming transformed into petechial areas. Consequently, the infectious erythemata of typhoid fever whose appearance and evolution are irregular may sometimes be confounded with the cutaneous manifestations characterizing certain infectious processes. Usually, however, an attentive examination of the patient will remove all cause for mistake, the essential thing being to remember that typhoid fever may be accompanied by an erythema.

The degree of gravity of these infectious erythemata of typhoid has been variously appreciated by different observers. Some have regarded them as of little importance, without any influence on the evolution of the typhoid fever and some have even gone so far as to maintain that they were a sign of approaching recovery. Chédevergne supposed that the cutaneous congestion appeared to announce the imminence of a crisis, while Raymond and Nélaton in the three cases under their care did not note any unusual symptoms at the time the eruption occurred. On the other hand, Hutinel, Le Gendre, Galliard and others are far from accepting this view on account of the numerous deaths which followed the erythema in the cases of typhoid fever under their observation. The typhoid assumed a very bad course after the appearance of the exanthema. In two cases reported by Pons, of Toulouse, death occurred shortly after the cutaneous manifestation arose. Although there is this diversity of opinion the reason for it can be explained, if these eruptions are divided into two categories, namely, the early benign erythemata and the late severe erythemata, the observers who have met with rashes at the onset of typhoid were dealing with essentially mild types of the exanthemata, while in the second case the exanthemata were observed during convalescence from typhoid and are remarkable for their peculiar severity and aspect. Consequently the prognosis should be based upon the date of the appearance of the rash, and according to circumstances it will be favorable or reserved. It likewise must depend upon the degree of vital resistance offered by the patient. The early appearing rashes do not have an appreciable influence on the evolution of the typhoid; the late ones, on the contrary, are to be regarded as real complications and if the patient recovers the convalescence will be long and tedious.

THE FUNCTIONAL LOCALIZATION OF THE INTERNAL CAPSULE.

THE opinions expressed in most of the classical text books relating to the functional localization of the various parts of the internal capsule in man are far from being as solid as the perusal of these works might lead are to suppose. The only localization which seems clear from the analysis of former anatomoclinical documents is a motor localization. All the others, those of choreiform movements, and disturbances of speech, sensibility, and intelligence, are either uncertain or erroneous. So far as motor phenomena are concerned it is certain that the internal capsule is a route for the passage of the fibers of projection which starting from the Rolandic region of the cortex, go to the muscles of the face and limbs on the opposite side. Generally speaking, the fasciculi destined for the innervation of the face travel through the internal capsule at the level of its genu; those destined for the innervation of the limbs go through the pars occipitalis. But there are some instances of lesions of the pars frontalis which resulted in paralysis of the limbs on the opposite side and lesions of the pars occipitalis which provoked facial paralyses, all of which seem to show that there are individual variations in the arrangement and assumed during their capsular passage, of the various functionally distinct fasciculi, similar to those often existing in other portions of the nervous centers, especially in the intersection of the anterior pyramids.

Paralyses of capsular origin affect, according to the extent and topography of the lesions giving rise to them, the types of pure monoplegia—laryngeal, facial, brachial, crural—associated monoplegias—linguofacio-pharyngeal, brachiocrural — or total hemiplegia. These paralyses are usually permanent and are accompanied by secondary contractures with degenerations of the pyramidal fasciculi. With the paralytic phenomena, which form the principal and almost constant symptom of destructive lesions of

the internal capsule, disturbances of speech, choreiform phenomena, disturbances of the sensibility, emotivity, and intelligence often become associated. The disturbances of speech depending on capsular lesions do not belong to the class of true aphasia. They are symptoms of a purely motor order that compose, according to the degree, the capsula dysarthria or anarthria. Consequently, there is no fasciculus of aphasia in the internal capsule. The choreiform phenomena are observed only when the provocative lesions of the paralyses attain the pars occipitalis, nevertheless it is not possible to distinguish a distinct fasciculus in the pars occipitalis the lesion of which alone can provoke hemichorea without a concomitant paralysis.

The disturbances of sensibility consist either in hemihypoesthesia—decrease of the tactile sensibility to both pain and heat—or total and complete sensitive-sensorial hemanesthesia of the Türck-Charcot type. The latter appears to be due to an hysterical coorganic association. It is impossible to locate the former anywhere but in the motor area of the limbs. Therefore, it is not possible to determine a distinct fasciculus in the pars occipitalis a lesion of which could result in hemianesthesia without a concomitant paralysis.

Certain disturbances of emotivity, especially spasmodic laughing and crying, appear to be susceptible of development in cases of limited lesions of the pars frontalis of the capsule, but so far there exists but one confirmatory case. The disturbances of the intelligence do not assume any special character from the capsular location. They in no way differ from those occasionally occurring with any sort of destructive lesion of the cerebral region, so that there cannot be a capsular intellectual fasciculus. But the data at hand relating to limited lesions of the internal capsule are still so few that new documents are necessary in order to throw light upon the physiology and pathology of this point.

Treatment of Persistent Vertigo With Adrenine.

Vernet writes extensively on this subject in *La Presse Médicale* for July 10, 1920, xxviii, 47. He defines this affection as "labyrinthine disequilibration." At the base of every vertiginous sensation is a labyrinthine phenomenon, vasomotor or toxic, and having a sympathetic or endocrinic point of departure. Therefore if adrenine can be exhibited at the right moment it should be productive of good results. The common association of tinnitus, deafness, and vertigo is due to angiospasm. This the author terms the "syndrome of Lermoyez" otherwise "audible vertigo." It is present in a sense in Ménière's disease in which hemorrhage into the labyrinth initiates the triad of symptoms. Different vessels may be involved on different occasions, the cochlear or vestibular arteries, and with spasm in the territory of the former, vertigo is absent, the other symptoms being present. There are as many causes of vertigo as there are causes of vasomotor labyrinthine manifestations. Here belong the numerous toxic, sympathetic, endocrinic, traumatic, and local causal factors. The author among the great variety of medicaments for vertigo has never seen adrenin mentioned. Yet this substance on theoretical grounds is the drug of which the most should be expected. Naturally it cannot control cases such as vertigo due to tænia which subsides instantly upon expulsion of the worm. But it is a regulator of blood pressure and has moreover a special selective action on the terminal filaments of the sympathetic nerves. Finally it is an "antitoxic" according to the author; although his reasons for such belief seem far fetched. In vertigo he has used this drug for the past four years and with satisfactory results; although at times it has been necessary to give pilocarpine in the capacity of antidote or antagonist. He prefers the buccal route, from five to twenty minims of the 1-1000 solution every two hours for an indeterminate period. It is clearly not given as a emergency measure but to combat a permanent condition.

Influenza and the X-Ray.

Schinz of Zurich sums up the radiology of grippe in the *Schweizerische medizinische Wochenschrift* for July 8, 1920, as follows: One of the most familiar finds is massive, confluent bronchopneumonia which is seated by preference in the lower lobes and causes a massive area of percussion dullness, although made up of innumerable smaller or larger detached foci. Next in order and often inappreciable by physical diagnosis is central bronchopneumonia which is difficult to distinguish from the corresponding type of croupous pneumonia. Third in order is miliary bronchopneumonia; not recognizable clinically but readily visible in radiograms; it is never of single occurrence being always combined with one of the other types. In the fourth place is mentioned the homogeneous pseudolobular type, in which the homogeneous shadows are due to total confluence of hemorrhagic or fibrinous foci; these areas pass by gradation into the massive bronchopneumonic forms. Many *x*-ray pictures have a marked resemblance to tuberculosis. In both diseases we see the same polymorphism. But in grippe there are no cavities, not old peribronchitic processes, nor apical involvement. But tuberculosis, mostly of one lung, may sometimes develop in a subject with pneumonic foci in the lower lobes. Other radiological finds concern pleuritis and empyema and in this connection spontaneous pneumothorax is an important complication which may arise in at least four ways—as a result of rupture of the lung from coughing, rupture of interstitial emphysema vesicles, perforation into the pleura of a subpleural pneumonic focus, and rupture inwards of an empyema. These are not theoretical types for the author exhibited cases under each form.

Eserine in Sympathicotonus.

Cheinisse mentions in *La Presse Médicale* for July 10, 1920, xxviii, 47, a recently published volume by Guillaume on the sympathetic. This is fruitful in suggestion for the French must confess that they have been irresponsive to the newer literature of vagotonus and sympathicotonus. Vagotonics re-

spond strongly to pilocarpine and atropine while sympathicotonics are susceptible to the action of adrenalin. As is well known there are mixed syndromes. Recently Moutier has published an article on "solar crises" and their treatment by eserine. These crises are closely akin to sympathicotonus, a condition in which we encounter tachycardia, vasomotor instability with hot flashes, dilation and atony of the stomach, vascular hypertension, epigastric hyperesthesia, mydriasis, etc. In the solar crises Moutier lays emphasis on the epigastric pulsation of the aorta. Since atropine is the remedy indicated in vagotonia, it occurred to him to test eserine in these sympatheticotonic crises. Mougeot had already tried it out in tachycardia—hypodermics of an oily solution of the salicylate or sulphate. An Austrian, Kaufmann, had some years ago independently recommended physostigmine in tachycardia, this being an echo of the use of this alkaloid in postoperative ileus by Von Noorden in 1901. The remedy appears to be able to cut short paroxysmal tachycardia, at times in association with strophanthus. Moutier has recommended the buccal use of eserine or physostigmine in increasing doses for sympathicotonic phenomena. In but one case was too much of the alkaloid given, but there were no serious consequences. Loeper, a modern writer on drug action, is opposed to eserine as being uncertain and unstable, but he has apparently not used the salicylate which has given good, dependable results in Moutier's hands.

Physical Exercise and Physiology.

Gymnastics has for the most part been an empirical study but several important works have appeared especially of recent years which have sought to place physical exercise on a sound physiological basis. Of the older writers Lagrange is the best known, his book on the physiology of physical exercise going back to 1889. The most recent book in this field is that of Bainbridge, 1919. In the *Giornale di medicina militare* for June 1, 1920, Angelucci contributes an important study on the physiology of physical education, which is of added interest because he shows that Mercurialis, one of the greatest of practitioners of the XVIth century, was the pioneer in this field. Born in 1530, he held the chair of practical medicine in three of the Italian Universities and was knighted by Maximilian of Austria, whom he had cured. He wrote pioneer works on the diseases of women, the diseases of children—and although the author does not mention it, diseases of the skin—on the pestilences, poisons, hydrophobia, etc. But his *magnum opus* was "De Arte Gymnastica" which went through three editions in Venice besides several translations. It is said that he adhered too closely to Galen for a man of his century. He followed the latter's classification of gymnastics by repudiating athletics as an end in favor of medical gymnastics or in other words physical education. He also borrowed from Avicenna who wrote extensively on the subject. The illustrations in his book have as subjects activities of the Greco-Romans as seen in the Olympic games, etc. But Mercurialis was justified in quoting the ancients freely in a subject in which they were so preeminent, and the knowledge and practice of which had long been ignored; and his activities here are strictly pertinent to the period of the Renaissance which witnessed the revival of learning in Europe.

Organotherapy in Froehlich's Syndrome.

The old pronouncement that organotherapy is valueless in affections due to compression of the hypophysis is evidently only partly true, according to experience in two cases of De Quervain in (*Schweizerische medizinische Wochenshrift*, July 15, 1920, i, 29). The first case was in a boy of ten known to have hypophysis tumor. The left eye had become quite blind, with vision impaired in the right. There was headache and very large sella. Diabetes insipidus was marked. The appearance was typical of Froehlich's disease with intelligence intact. Neither hypophysis nor thyroid tablets gave material relief. Surgical intervention after some years was apparently limited to decompression. The *status quo ante* returned with death under symptoms of compression. Autopsy revealed a calcified epithelioma of the duct with destruction of most of the hypophysis. The second patient was a girl of twelve who at the age of seven began to evolve the picture of Froehlich's disease. The sella appeared to be normal. At the period of complete evolution the child resembled a fat woman at the menopause. Hypophysis extract was begun, alternating the anterior and posterior lobes and tablets and fresh substance over a long period. The subject began to lose weight while she began to increase in height. The gain was over 12 cm. in one year as against 10 cm. in the preceding four years. While there have been remarkable changes for the better it is yet possible to recognize the Froehlich case in the physique. The menses have not yet appeared. The treatment appeared to show that injury of the posterior lobe will cause fat deposit and that the same lobe also plays a rôle in skeletal growth, although recently this has been assumed to be associated with the anterior lobe only.

News of the Week.

Medicinal Springs in Japan.—Japan is making an investigation of her natural springs, with a view to making a national asset of them. There are said to be 601 cold springs and 1,103 hot springs, many of which are mineral springs having valuable medicinal qualities.

Relief for Chinese Famine Sufferers.—The American Red Cross has appropriated $500,000 with which to fight the famine in the Pekin, China, district.

Typhus on Liner.—A case of typhus fever in the steerage caused the Holland-America liner *Noodans*, arriving at New York from Rotterdam last week, to be held at Quarantine.

Forty-one Millions Spent in Near East Relief.—The Near East Relief has spent forty-one millions and saved more than half a million lives, according to Charles V. Vickrey, secretary of the Executive Committee, who recently returned from a tour of inspection in Armenia and Syria. The committee now occupies more than 300 buildings as hospitals, schools, and orphanages. In June

there were 54,600 infants in orphanages and 110,000 children living in their own homes were under the care of the committee. Not one penny of loss, it is stated, has resulted from dishonesty.

Dysentery in Vienna.—An epidemic of dysentery, afflicting thousands daily, according to press news, is attributed to spoiled cornmeal used in making bread.

Woman Leper Nurse Decorated by France.—Mlle. Safino, who for twenty years has directed the lepers' institution at Manankavaly, Madagascar, has been awarded the Cross of the Legion of Honor by the French Government.

Death Claims Paid by War Risk.—The Bureau of War Risk Insurance announces that the sum of $1,154,911,719 has been paid out in death claims, and $29,577,540 for disabilities, during and since the war. Up to August 31 the bureau had issued $40,000,000,000 in war risk insurances.

Occupational Therapy for Tuberculous Ex-Service Men.—Reports from the Government tuberculosis sanatoria of the United States Public Health Service to the Surgeon General just made public, demonstrate conclusively the great value of occupational therapy as an adjunct in the treatment of discharged and disabled soldiers. In fact, as carried out by the experienced reconstruction aides of the U. S. Public Health Service, occupational therapy, consisting of mental work and manual handicraft for curative and diversional purpose, promises much in the medical care and treatment of discharged and disabled soldiers now being cared for by this service. According to this report, out of 392 patients admitted to one sanatorium, 263 took occupational therapy and 129 did not. Of the former only two patients left the hospital against the advice of physicians in charge. On the other hand, of the 129 who did not take occupational therapy, 83 either deserted or left the hospital against the advice of the physicians in charge. This is less than 1 per cent. among the former, as against 65 per cent. among the latter class of patients. The Public Health Service operates the largest unit now engaged in occupational therapy and physiotherapy, over 300 expert aides, mostly women being employed.

Extension of Red Cross Work.—The American Red Cross has announced the establishment of a Department of Health Service and an extension of its nursing service. The organization now has 36,000 nurses on its rolls working in more than 15,000 communities. In order to increase the number of qualified public health nurses 288 scholarships have been established and 67 loans have been made from the national fund to public health nursing. In addition approximately 250 scholarships have been awarded by the various chapters and funds have been given to various universities. Development in class instruction in home nursing has increased threefold during the year, the number of women taught having increased from 34,033 to 93,093.

Automobile Deaths in New York City.—During the month of September there were 89 persons killed by motor vehicle accidents, 49 of whom were children under sixteen years of age, according to the National Highways Protective Society. The number for the entire State was 202, the largest number ever recorded for one month in this State.

Typhoid Fever in Adirondacks.—An epidemic of typhoid fever at Conifer, a lumber hamlet in the Adirondacks, is reported to have caused several deaths, while scores are ill. The State Board of Health has sent a unit of nurses and physicians to the town.

New York State War Service Hospital.—Governor Smith has appointed Dr. Thomas W. Salmon of New York City as the medical representative on the commission which is charged with the construction of the hospital for the care of the World War Service men suffering from mental diseases. The extraordinary Legislature appropriated $3,000,000 for the purpose.

Dr. Jacques Loeb of the Rockefeller Institute for Medical Research will deliver the first of the Harvey Society Lectures at the New York Academy of Medicine, Saturday evening, October 16, 1920. His subject will be "The Proteins and Colloidal Chemistry."

Dr. Jacob Rosenbloom has removed his office to 120 West Seventieth Street.

Dr. Jacob Diner has removed his office to 344 West Eighty-fifth Street.

Dr. Robert Abrahams has removed his office to 260 West Seventy-second Street.

Dr. Abr. L. Wolbarst has removed his office to 792 Lexington Avenue.

Miss Abby Henrietta Campbell, founder of the Faith Home for Incurables in Brooklyn, died recently after a long illness, at the age of eighty-four. She had been superintendent of the institution for more than forty years. The home is at present caring for seventy inmates.

Obituary Notes.—Dr. ANNA FORREST ROWE of New York City, who died recently, was the founder of the Lucretia Mott Dispensary, the first complete hospital and dispensary for women in Brooklyn. Dr. Rowe was graduated from the Women's Medical College for the New York Infirmary for Women and Children in 1880.

Dr. EDWARD J. CARROLL of Brooklyn, N. Y., died Oct. 2. He was graduated from New York University Medical College in 1882, and was at one time physician to St. Catherine's Hospital.

Dr. ADOLPH GEHRMANN of Chicago died Oct. 4 at the age of fifty-two. He was graduated from Northwestern University Medical School in 1890. He was professor of bacteriology and hygiene at the College of Physicians and Surgeons, and at one time was superintendent of bacteriology for the city of Chicago. Dr. Gehrmann was a member of the American Medical Association, the American Public Health Association, and State and local societies.

Dr. FREDERICK CLARK of New Brighton, Staten Island, died Oct. 5 at the age of seventy-two. He was graduated from the College of Physicians and Surgeons, New York City, in 1873. He was one of the founders and a life member of the Richmond County Medical Society.

Dr. HENRY STEWART, retired naval surgeon, of Canandaigua, N. Y., died at Clifton Springs Sanitarium Oct. 4, at the age of seventy-three. He was graduated from the New Orleans School of Medicine in 1868.

Correspondence.

LONDON LETTER.

(From Our Own Correspondent.)

LONDON, September 17, 1920.

Some of the Work of the Ministry of Health.—The first annual report of the Ministry of Health has recently been issued and in it the multitudinous activities of the local authorities are comprehensively and statistically reviewed. It supplants the reports hitherto annually sent out by the Local Government Board. Matters affecting the public health are exhaustively, critically and, of course, intelligently discussed by those who know well whereof they speak. It is a valuable and interesting document and proves conclusively that the hearts of the officials are thoroughly in their work. As a survey of the health conditions of England and Wales it is splendid, and undoubtedly if the ministry were not handicapped in many ways, financially for instance, and if there were not so many immense problems to solve, great headway would soon be made. But at the present time Great Britain like all European countries, although perhaps, to a less extent, is rent by internal strife and domestic questions must be largely left in abeyance until some sort of settlement is made. In the meantime the Ministry of Health must mark time waiting for those happier days. As said before, the report is full of meat and moreover should provide almost as interesting reading to American as to British medical men. The work of the Ministry is outlined in detail. Up to March 31, 1920, the Ministry and their predecessors had approved 395 dispensaries for the treatment of tuberculosis, of which 362 had been provided by local authorities. There were also 388 approved residential institutions with 15,781 beds, which is an addition to the available accommodation of 2,258 beds during the year. Up to the same date proposals had been submitted to the Local Government Board and the Ministry for the provision of 9,830 additional beds, including 1,263 for the use of patients in the County of London. Local authorities were responsible for the greater part of the increases. Up to March 31, 1920, capital grants amounting to £893,999 had been definitely promised in aid of the provision of institutions in England for the treatment of tuberculosis, and of this sum £445,433 had been paid. This represented an increase of £444,461 in the total amount promised, and of £81,663 in the total amount paid as compared with the previous year. The total number of notifications of pulmonary tuberculosis for 1919 was 67,123, and other forms 17,775, as compared with 79,025 and 20,215 respectively for 1918. Deaths from pulmonary tuberculosis during 1919 numbered 36,662, and from other forms 9,650, the respective figures for 1918 being 46,077 and 11,996.

In connection with consumptive ex-service men it is stated that the difficulties which will arise in the absorption of these men into industries are considerable, and probably the only method by which many of the men will be able after training to earn a livelihood for any prolonged period, without frequent relapse and ultimate permanent breakdown, is by being placed under such special conditions and in such surroundings as will afford shelter from the full stress of competitive industry by enabling them to live in a village settlement or an industrial colony established on lines especially designed for these purposes. The Ministry are accordingly in communication with the Treasury on the whole question of the establishment of village settlements and other kindred arrangements under which the tuberculous patient would, after training, be able to be employed under specially sheltered and favorable conditions. Of 57,361 samples of milk analyzed during the year 11.1 per cent were found to be adulterated, the percentage in London being 7.7. The comment is made that "although several successful prosecutions are recorded which resulted in large fines being imposed, there is evidence that difficulty is frequently experienced in obtaining convictions." Referring to the fact that during 1919 infant mortality reached the record low rate of 89 per 1,000 births, the report states that while this record is no doubt due to a variety of causes, including the favorable climatic conditions, the comparative prosperity of the wage-earning classes and the continued depression of the birth rate there can be no doubt that maternity and child welfare work has materially contributed to its reduction and the low rate is a substantial encouragement to further efforts in the same direction.

The housing problem is one that still remains to be solved and under present conditions it seems almost to be unsolvable. When workmen's houses in agricultural districts cannot be built at a less cost than £700 the question is who is to pay the rent which will amount to £50 a year or thereabouts. Although the agricultural laborer now earns about £2.10., or so, a week he cannot afford to pay such a rent and maintain a family at existing prices of all the necessaries of life. Half the rent is the utmost that he can pay, so that out of his own pocket he cannot hire the cottages that are being erected. But they are built expressly for him and as there are no others available he must live in them. The Ministry of Health have proposed that the remainder of the rent should be paid out of the rates, which means that the overtaxed middle class must make up the deficiency. Among the methods favored by the Ministry of Health for the reduction of the cost of building is the use of substitutes for brick and mortar and of these the hollow concrete blocks are perhaps the favorites. A bungalow made of these materials can be built for £300, largely with unskilled labor, but the trade unions would step in and prevent this. So it comes about that no one can either afford to buy bricks or to do without them. Some time ago the Ministry of Health proposed to medical officers that the housing section of their annual reports should be issued separately. As the *Lancet* of September 11, in its Housing Notes points out, Dr. Herbert Jones, medical officer of health for the Herefordshire Combined District, has complied and in the annual report, 1919, issued August 20, 1920, makes a comprehensive survey of present housing conditions. In half the

parishes more houses are needed, and the schemes submitted to the Government, even were they now completed, would not meet the need. Regarding the standard of accommodation, Dr. Jones would have each house built on a quarter-acre plot and contain parlor, kitchen, wash-house, scullery, bath, and three bedrooms. By discussing the question of "women's institutes" and other organizations he has discovered a unanimous opinion in favor of both parlor and bath. The Ministry of Health are pledged to deal with the housing question first, and as said before it appears almost impossible of solution.

Extensions to Hospitals.—In the first week of September the Duke of Northumberland opened the Orthopedic Hospital extension of the Royal Victoria Infirmary, Newcastle-on-Tyne, for the treatment of disabled ex-service men and civilians. The hospital has been actually in operation twelve months under the Ministry of Pensions. There are 540 beds, and 1,563 patients have been treated. The sum of £8,000 raised as a memorial to the late Duke of Northumberland was given to the fund, to which workmen also contributed generously. The Duke said the building cost £160,000, and nearly all had been raised from contributions. Were it not for the progress of the science of orthopedics, half the men on whose behalf the King was appealing would have been unemployable. The results of reconstruction had been somewhat disappointing but too much had been expected. Consequent on Mr. Seymour Berry's gift of £10,000 important temporary extensions to Merthyr General Hospital have been commenced.

Research in Tropical Diseases.—Recently new laboratories for research into the origin and treatment of tropical diseases were opened at Liverpool. The laboratories are named after Sir Alfred Jones, the Liverpool ship owner, who took a great interest in the work done in the investigation of tropical diseases at Liverpool, and made provision in his will for the erection of a laboratory. The chairman, Sir Francis Danson, said at present they were investigating yellow fever in the laboratory which they had established at Manaos, and they had also obtained from the Colonial office the long lease of a site for another laboratory at Sierra Leone. They were expanding in Liverpool, and having obtained from the university the necessary land, they had erected this new building.

Postgraduate Study for General Practitioners at St. Andrews.—A short course of postgraduate study for general practitioners will be given at the Clinical Institute, St. Andrews, under the direction of Sir James Mackenzie, commencing on October 11. The course to which only a limited number of members will be admitted will consist of lecture demonstrations dealing with the symptomatology of disease in its early stages, and will be supplemented by demonstrations on matters of clinical interest in anatomy, physiology, chemistry, bacteriology, ophthalmology, and radiology.

Industrial Blindness.—The returns of the civilian after-care department of the National Institute of the Blind show Lancashire to have 4,202 sightless persons as compared with 2,593 in Yorkshire. This difference is largely due to the character of the industries carried on in the two counties. Mining and steel industries are two highly dangerous occupations, especially with regard to the eyes of the workers. In spite of the attention given by the local authorities to the prevention of injuries of this nature, it appears that the number of those who have lost their sight from industrial causes has increased during the past ten years. On the other hand, the compulsory notification of ophthalmia neonatorum has resulted in a great diminution of infantile blindness.

Some Medical Aspects of the National Health Insurance Act.—A memorandum on this subject by Sir James Mackenzie is published as an appendix to a report of the Inter-Departmental Committee appointed to consider and report upon the form of medical record to be prescribed under the terms of service of insurance practitioners. It begins by pointing out that the purpose of the National Insurance Act is to provide for the prevention and treatment of ill health accruing among the industrial classes of the community. This purpose is effected for the most part by the employment of those who have under their care the sick and injured, i.e., through the agency of the general practitioners of the country; and the success of the act depends upon the degree of efficiency with which these agents can carry out their work, especially in the diagnosis and treatment of the ordinary disabling diseases which affect the industrial community. 2. Legislation on matters of health depends upon the state of medical knowledge at the time and as medical knowledge is not complete or stationary at any one time, but is defective and transitionary, it follows that the regulations must be drawn up in such a way as to enable them to be adapted to advances in medical knowledge, and also to provide and encourage opportunities and efforts for progress in medical science. The present defects in medical knowledge are fully apparent only to those who are actually engaged in the work of general practice. Sir James Mackenzie goes on to state that the memorandum has been drawn up with a view to indicate the principal defects in medical knowledge which exist at the present time and which impair the success of the act, and also to indicate some steps which can be taken to remedy them. The memorandum is too long to quote in its entirety so a summary will be given and a condensed account of the methods pursued at the St. Andrew's Institute for Clinical Research, which was inaugurated and is directed by Sir James Mackenzie. This is the summary: (1) The present phase of medical knowledge is defective, because the classification of disease is largely based upon pathological changes discovered after death, which bear little or no relation to the clinical manifestations of ill-health and no relation to the early symptoms of disease which occur before structural changes can be recognized, (2) Advance in knowledge along the right lines can only be effected by making use of the opportunities of the panel doctor. (3) Encouragement must be given to the panel doctor to make use of his opportunities for improving medical knowledge, (a)

by encouraging him to keep brief records of his cases and of the symptoms presented on the lines indicated; of the effect of treatment upon them, and of the continuous history of his cases. (b) By issuing to him from time to time notes upon the mechanism and significance of symptoms. (4) By improvements in medical education in affording some instruction on clinical medicine as studied and treated in general practice apart from its study under hospital conditions. (5) In view of notes of cases kept by a practitioner as indicated, certificates of fitness or unfitness for work should be accepted apart from a definite diagnosis in the numerous cases in which a true diagnosis is not as yet obtainable. 6. By the coordination of workers, clinical and laboratory, the progress of medicine can be favored, and the more skilful treatment of panel patients facilitated. The methods pursued at the St. Andrew's Institute are as follows: (1) Each clinician has a private room in the institute. This is reserved from 11 to 1 on Mondays, Wednesday, and Thursdays for research cases. During the rest of the day each practitioner may use the private room as a consulting room. The panel practitioners who do so have the advantage of the use of the scientific departments whenever required. An index file and cards are provided in each room upon which brief notes are kept of each private or panel patient. These cards will, in time, form records of the life history of each patient. In the event of a patient removing to another district these notes can be sent to the new attendant. (2) Cases for research are selected from his own practice by each member of the clinical staff. These are, in the first instance, seen by him, and he is at liberty to consult Sir James Mackenzie or any colleague at any stage of the case. If any special investigations are required, these are carried out by the staff of the special departments. (3) On Tuesday afternoons some special subject, arranged beforehand, is discussed by a general meeting of all members of staff. (4) On Friday afternoons the whole staff discuss the cases seen during the week and any suggestions for investigation of any case made at that meeting are proceeded with and added to the record. The principle upon which Sir James Mackenzie proceeds is prevention of disease by means of early diagnosis and efficient treatment, so that the malady does not gain a firm foothold, but he recognizes, as indeed do all discerning medical men, that the general practitioners, who alone have the opportunity of observing early symptoms, must be trained in the diagnosis of such symptoms ere they are able to detect them or appreciate their significance. He also points out that there exists among the medical profession a defective knowledge of drugs and a defective knowledge of prognosis. He has founded the St. Andrew's Institute with a view of remedying these defects as far as is possible, or rather of showing how they or, at least, some of them can be remedied. The work, of course, is largely experimental, but there is no doubt that it is a move in the right direction and if successful will almost revolutionize the practice of medicine throughout the world.

Progress of Medical Science.

6. Medical Judgments. H. W. Marshall.

4. Enlarged Mesenteric Lymph Nodes.—Howard M. Clute states that the symptoms of enlarged mesenteric glands vary with the pathological condition of the glands, with the age of the patient, and with the relation of other organs to the glands involved. In both children and adults they constitute one of the causes of abdominal pain, which may give no hint as to its origin before an exploratory laparotomy is done. In the early stages of the disease in children there is often a history remarkable for its vagueness, with little pointing to the real source of trouble. Adequately treated, the prognosis in enlarged mesenteric nodes is good. No deaths and no recurrence of symptoms after the removal of the nodes have occurred in the two cases that formed the basis of this study. The principles governing the treatment are the removal of the focus of disease and the care of the general health of the patient postoperatively. Conservative hygienic treatment may well be tried first in cases of this nature. Conservative measures failing, however, operative removal is indicated.

11. Medical Men in the American Revolution. (*Concluded.*) Louis C. Duncan.

4. When Is Gonorrhea Cured?—Maurice Meltzer answers the question asked in the title of this paper as follows: 1. A cured patient should present no morning drop or urethral secretion at any time of the day. 2. Microscopical examination should show no pus or gonococci in the urine, prostatic, or seminal vesicle smears. 3. The urine should be clear, though in some cases small noninfective desquamating shreds may persist. 4. The urethral lumen should be free from any narrowing or stricture formation. 5. The complement fixation test should be negative in conjunction with the other findings. 6. In doubtful cases the secretions from the genitourinary organs should be cultured to prove the absence of gonococci on suitable culture media. 7. Cystourethroscopic examination should show the urethra free of lesions.

7. The Intensive Administration of Arsphenamine.—Herman Goodman bases this contribution on the intensive specific therapy in eighty hospitalized syphilitic negro patients, the cases being divided among the syphilitic periods as follows: Primary syphilis, 28 cases; silent generalization, 23 cases; secondary syphilis, 16 cases; latent tertiary, 4 cases; active tertiary, 9 cases. In primary cases the diagnosis was made by the demonstration of the *Spirocheta pallida* where the diagnosis was at all doubted clinically. The intensive arsphenamine treatment in these cases was administered as suggested by Pollitzer. The clinical results were immediate in all uncomplicated syphilitic manifestations. The infectiousness of the patient was reduced thereby much more quickly than with the same amount of the arsphenamine introduced intravenously by the so-called intermittent method. The changes in serology were

most encouraging, but no attempt is made by the writer to base conclusions on them. With no further precaution than that taken for the administration of arsphenamine intermittently, the eighty men were given this intensive form of treatment with excellent results. He does not hesitate to recommend the procedure for more general use by those especially skilled in the application of arsphenamine as generally administered. The public health value of this method is emphasized. The period of hospitalization of infectious syphilitic persons is much reduced thereby, which is an important consideration in the prophylaxis of syphilis by treatment.

9. Fatal Postarsphenamine Jaundice.—Albert S. Hyman, in a review of several thousand doses of arsphenamine given at the Venereal Clinic of the Long Island Hospital, was able to demonstrate seven cases of toxic jaundice which were undoubtedly due to this specific drug. All but one of the patients recovered. This case is reported.

4. The Segregation of Pneumonia.—Thomas S. Southworth expresses the view that the obligation is imperative to anticipate the day, which he considers not far distant, when the movement to control the scourge of pneumonia may make the retention of such cases in a general ward as repugnant to the medical sense of propriety as the retention of an open case of pulmonary tuberculosis.

9. The Complement Fixation Reaction in Tuberculosis.—Watkins and Boynton make a statistical report of 6,500 reactions, discussing briefly the two or three fundamental points in dispute regarding this test. They found the Miller antigen serviceable, practicable, and efficient for the complement fixation test in tuberculosis. The reaction is specific for tuberculosis, and, when positive, should be interpreted as indicating tuberculosis of some degree of activity. When the Wassermann and tuberculosis fixation reactions are both positive, they should be interpreted without relation to each other. The positive fixation reaction can be interpreted as indicating tuberculosis, either active at the time, or recently active. The focus may or may not be of clinical significance, which fact must be determined by other means. The negative fixation reaction indicates either absence of infection, excessive activity of the disease, exhausting the antibody, or arrest of the disease with spontaneous disappearance of antibody no longer required.

10. Venipuncture in the Treatment of Certain Diseases of the Skin.—Kingsbury and Bechet believe that venipuncture is of occasional value in certain cases of psoriasis, erythema multiforme, and dermatitis herpetiformis. It is of great value in the treatment of urticaria, and in their hands afforded more relief in severe cases of that disease than any other therapeutic method.

4. An Experimental Study on the Origin of Idiopathic Nephritis.—Day and Clarke detail observations which involved experiments with renal substance; investigation of urine; characteristic organisms; injection of cultures into animals; experiments with other organisms; and trial of vaccines. From these investigations the following summary is drawn: 1. From the urine of patients with "idiopathic" nephritis and from the kidney of a case of fatal nephritis, bacilli of intestinal type have been isolated in pure culture. 2. Injection of these cultures and subcultures into animals provokes acute nephritis. 3. From the kidneys of these animals in the earlier stages of nephritis the bacilli injected have been recovered in pure cultures. 4. Injections of cultures obtained from animals infected with these bacilli have reproduced the disease in other animals. 5. The nephritis induced runs a somewhat prolonged course, and is accompanied by acute degeneration of liver cells and an enlargement of the spleen in the early stage. 6. In human cases of nephritis treatment with appropriate vaccines has caused rapid amelioration. 7. In some cases of nephritis a secondary or an independent infection of the urinary system may be present and obscure the original cause.

6. Notes on the Treatment of Recurrent Malaria by Novarsenobenzol.—J. Norcott d'Esterre assigns the following reasons for using novarsenobenzol in recurrent malaria, twenty cases of which so treated are reported: 1. Because it has been conclusively proved that the malarial fevers are protozoal infections, infecting the red corpuscles of mammals, reptiles, and birds. 2. Because the organic compounds of arsenic in its trivalent form are more potent in action upon protozoa. 3. Because it is known to destroy the *Spirochæta pallida*, the balance of opinion now being distinctly in favor of the *Spirochæta pallida* being a protozoon.

6. *X*-Rays in the Diagnosis of Tumors of the Thorax.—Robert Knox holds that radioscopy is most useful in a preliminary investigation because it offers a great deal of useful information. The patient should be screened in as many positions as possible, and all variations in size and shape noted. Pulsation should be most carefully looked for because it is so very valuable in the differential diagnosis to know that the tumor pulsates and whether the pulsation is direct or transmitted. On this point alone a diagnosis can often be made. Negatives should always be taken as a final step in the technique, and it is often well to take these in several positions. Consideration of a number of negatives from different angles will afford valuable aid when one must sum up and give an opinion on the nature of a shadow.

7. The Diagnostic Value of the Renal Outlines.—S. Gilbert Scott summarizes as follows the method of de-

termining the relation of abnormal shadows to the kidney: (1) The outline of the kidney must be seen. (2) An abnormal shadow lying *outside* this cannot be in the kidney. (3) If the shadow lies inside the limits of the outline, then it is necessary to compare the plate taken at full inspiration with one taken at full expiration. The respiratory excursion of the kidney is first measured, and the respiratory movements of the shadow under discussion are then compared. The direction of the movement of each is also noted. If the respiratory excursion and direction of the kidney and abnormal shadow are the same, the latter must be in connection with the kidney. A rule, therefore, can be formulated that if an abnormal shadow or shadows, no matter how small and insignificant they may be, lying inside the renal outline, move to the same extent and in the same direction as the kidney, they must be connected with it. This rule will apply to one or several shadows, and in this way it is quite easy to pick out from a number of shadows those that are of renal origin. In some cases the kidney may be fixed, and no respiratory excursion obtainable. If, however, it be possible to demonstrate that the shadow under discussion has moved in some direction or other, while the kidney has remained unaltered, the shadow must be outside the kidney. Once having diagnosed the presence of a stone in the kidney its correct position in the organ itself can be given, and a rough estimate made as to its size. Scott considers this method of localization invaluable where the shadow is extremely indefinite and doubt is felt as to its nature.

Relations Between the Temperature of the Expired Air and the Cutaneous Temperature.—Viale has undertaken to prove or disprove the conclusions of Galeotti and others to the effect that the temperature of the expired air depends on the vasomotor conditions of the lungs, and that there is a correlation between cutaneous and pulmonary vasomotor phenomena, both regions undergoing vasodilation and vasoconstriction at the same time. The measurements were made in mountain air with an altitude of 3,000 meters, the ambient temperature ranging from 8.5° shade to 13° sun. The author found the expired air to be at a constant temperature of 35° C., slightly higher than some figures of other experimenters. In another set of experiments the subjects were alternately clothed and nude. In the clothed body the expired air was always warmer than in the nude body, the difference being relatively small — in the neighborhood of 1° C. The differences in cutaneous temperature between the clothed and nude surfaces were very slight, but the former were always warmer. The author's figures agreed fairly with those of others. The effects of sun and shade and of the temperature of the circumambient air on cutaneous temperature and expired air temperature were also measured. When the body passed from sun to shade the temperature of the skin as well as that of the expired air fell, to rise again when the body passed back into the sunlight. The author therefore concludes that Galeotti's discovery is genuine.

Radiation of the Hypophysis for Bronchial Asthma.—Ascoli and Fagiuoli mention the possibility of radiation which can stimulate as well as retard endocrinic activity. The latter property of the rays is well known in comparison with the former. In raying a subject with dystrophia adiposogenitalis, after a certain amount of benefit had been derived from opotherapy, the rays being directed to the hypophysis, a distinct benefit accrued, so that the subject seemed on the way to recovery, but there is no mention of asthma or its relief. In a second patient with scleroderma there were evidences of a pluriglandular syndrome, but no improvement followed opotherapy. The authors then rayed the hypophysis and thyroid as well as the cutaneous lesions, with the result that some of the symptoms which pointed to hypophysis insufficiency improved. A patient with Graves' disease improved under radiation of the thymus and one with eunuchoidism under radiation of the hypophysis and testes. The hypophysis was next rayed in five cases of bronchial asthma. In none of these cases is there any mention of symptoms pointing to the hypophysis, nor of any motivation for the asthma. After the failure of adrenalin and pituitrin, the hypophysis was rayed with more or less benefit, and one might speak of cure in some of them, although attacks may of course reappear. In one case at least the combined adrenalin and pituitrin was of value equal to radiation in effecting the cure. The idea of raying the hypophysis for asthma came primarily from the improvement in asthmatic symptoms after raying the hypophysis for diabetes insipidus; and in part also, perhaps, because the good results of adrenalin suggested the pituitrin might also be of value.

Le Bulletin Médical.

September 11, 1920, xxxiv, 44.

Neurasthenics and Nosomaniacs.—Gallois would not use the term neurasthenic from the sufferer from imaginary ailments as visualized by Molière's comedy. Neurasthenia is a definite condition, having its causes and symptoms which distinguish it from other affections. The nosomaniac, on the other hand, has not been exposed to the causes of neurasthenia. He is usually wealthy, with nothing to take up his mind; he therefore becomes introspective and slight ailments are magnified through lively play of the imagination. But there are hybrids, and the true neurasthenic may become nosomaniac. The former has obsessions which interfere with the ordinary activities of life. He reads a page, but his reading has been automatic, and he fails to remember what he has read; he goes to the theater and can obtain no diversion. The nosomaniac can be readily diverted as a rule. The neurasthenic is troubled with insomnia and is therefore prevented from throwing off his obsession. He suffers much with helmet headache and in time becomes indifferent to everything—eating, walking, games, etc. There may be agoraphobia or asthenopia, which aggravates the difficulties of reading and walking. The nosomaniac has an entirely different mentality and is more of a nosophobic, always fearing that he has or will have some disease. He gets worked up about high blood pressure, failure of sexual power, and a score of other common conditions, and goes about from one specialist to another—he has made the fortunes of specialists. He is a comic figure in the world, while the true neurasthenic is a tragic figure. The nosomaniac may be tricked into a cure by suggestion, but the author does not sanction such a resource and would disabuse the patient of false conceptions by enlightening and convincing him of the unreality of his troubles.

Pancreatic Infantilism.—De los Torreros regards this condition as acquired and due to some one of the infectious diseases of childhood. Pancreatic infantilism is a pluriglandular syndrome and akin to others in which the thyroid or other organ predominates. The leading phenomena are emaciation from failure to utilize carbohydrates, status lymphaticus, leucopenia and mononucleosis. There is a special tendency to contract contagious diseases. In addition there are the evidences of pancreatic insufficiency in the stools. This syndrome has no connection with pancreatic diabetes. —*La Presse Médicale.*

Book Reviews.

DIAGNOSTIC METHODS, CHEMICAL, BACTERIOLOGICAL, AND MICROSCOPICAL. A Text-book for Students and Practitioners. By RALPH W. WEBSTER, M.D., Ph.D., Assistant Professor of Pharmacological Therapeutics and Instructor in Medicine in Rush Medical College, University of Chicago; Director of Chicago Laboratory, Clinical and Analytical. Sixth Edition, Revised and Enlarged, with 37 Colored Plates and 170 other Illustrations. Philadelphia: P. Blakiston's Sons & Co., 1920.

THE fact that this work has gone through six editions points to the appreciation with which it has been received. All care has been taken to include processes of investigation which are of proved value; mention is made of some which have not proved certain in the author's hands, while the references and bibliography enable a more searching scrutiny to be made. The volume is really a practical dictionary of clinical laboratory methods of research, and should prove of great aid to the general practitioner as well as to those who have the resources of a laboratory at their command.

It is to be hoped that the author will in a future edition collate the findings of Biochemistry and Pathological Chemistry and the effect of the colloids on solubility of excretory substances. If it be not hypercriticism to say so, more might be added to the section on the excretion of the chromogens in the urine as guides to the relative functions of liver and kidneys in intestinal stasis and toxin formation; and in the section on the blood no mention is made of Gruner's work on the morphology of the blood as an early indication in carcinoma and also in tuberculosis. Such careful work as the author has performed could only be enhanced by applying these diagnostic methods to the very early recognition of disease, and so bring to light such preventive-medicine efforts as are being tried clinically on Sir James Mackenzie's suggestion at St. Andrews. But for its present aim of diagnostic methods this volume is up to date and leaves little or nothing to be desired.

FORESTS, WOODS AND TREES IN RELATION TO HYGIENE. By AUGUSTINE HENRY, M.A., F.L.S., M.R.I.A., Professor of Forestry, Royal College of Science, Dublin. New York: E. P. Dutton & Company, 1919.

WHILE the major portion of this interesting volume is local in its application, pertaining to the afforestation of pit mounds and water catchment areas in the British Isles, the first four chapters have a more or less universal bearing. These chapters deal, respectively, with the influence of forests on climate; the sanitary influence of forests; forests as sites for sanatoria; parks in towns and municipal forests; trees in towns.

The book is particularly timely, for, as the author says in his preface, one effect of the war has been to bring home to thinking people the extreme importance of afforestation. For this reason the concluding chapters are devoted to a study of the afforestation of the extensive gathering grounds, from which so many centers of population obtain their water supply. Forty-nine illustrations and maps add interest to the text.

SIMPLIFIED INFANT FEEDING. With eighty illustrative cases. By ROGER H. DENNETT, B.S., M.D., Associate Professor of Diseases of Children, New York Post-Graduate Medical School; Attending Physician of the Children's Department, New York Post-Graduate Hospital; Assistant Attending Physician at the Willard Parker Hospital and Pediatrist to the New York Lying-in Hospital. With 14 illustrations. Second edition revised and enlarged. Philadelphia and London: J. B. Lippincott Company, 1920.

THE second edition is substantially the same as the first with a few minor additions. The author is greatly impressed with the value of boiled milk and advises its use, although the large majority of authors advise against the use of boiled milk. Cane sugar and malt sugar are advised rather than milk sugar which is advocated by so many American pediatrists. One is permitted to guess as to what the author means on page 19 where he states: "add one-fourth ounce sugar to the feeding" without specifying the kind of sugar to be used.

Of the new material in this edition, nine pages are devoted to dry milk. The laudations of this patent food could be excused if all the statements made were true. Careful clinical observations show that dry milk is excellent as a temporary expedient, but continued use of the same produces catarrhal alvine discharges. Concerning cereals on page 320 we find: "All cereals should be cooked *at least* three hours a day," and on page 322 we find the same advice: "Cook cereals three hours a day. It has been repeatedly proven by chemists that the large majority of cereals require but one hour of cooking, and the frequently used farina requires but one-half hour cooking.

The chapter dealing with caloric requirements of infants is well written. We find the caloric reckoning applied to most all of the clinical cases reported in the various portions of the book.

A MANUAL OF PHYSICAL DIAGNOSIS. By AUSTIN FLINT, M.D., LL.D., Late Professor of the Principles and Practice of Medicine and of Clinical Medicine in Bellevue Hospital Medical College, etc. Eighth edition, revised by HENRY C. THACHER, M.S., M.D., Assistant Attending Physician, Roosevelt and Lincoln Hospitals, New York. Illustrated. Philadelphia and New York: Lea and Febiger, 1920.

THE appearance of a new edition of this book is a welcome sign of the times. There has, of late, been a tendency to rely too much on laboratory work and on complicated instruments, and as a result, physical diagnosis has been neglected. The first edition of this work appeared some thirty-five years ago; for many years it was the favorite book on diagnosis; and, even now, with many larger and more pretentious books in the field, it holds a place of its own as a clear and concise guide to physical diagnosis. Students of to-day would do well to look at this classic of a quarter of a century ago.

ADVANCED LESSONS IN PRACTICAL PHYSIOLOGY FOR STUDENTS OF MEDICINE. By RUSSELL BURTON-OPITZ, S.M., M.D., Ph.D., Associate Professor of Physiology, Columbia University; Professional Lecturer in Physiology in Teachers College and the Extension Department of Columbia University. Illustrated. Philadelphia and London: W. B. Saunders Company, 1920.

THIS volume can be used either as a companion to the 'Text-Book of Physiology" by the same author, or independently. In either case it will be found a satisfactory guide to the laboratory work in Physiology now demanded of medical students in all the best schools. The volume contains about 200 pages, and it is divided into fifty lessons, covering the whole field of Physiology in so far as it lends itself to laboratory demonstration. The book is of a convenient size, is amply illustrated, will lie open at any given page, and contains numerous blank pages on which the student can add notes of his own work.

MASSAGE AND EXERCISES COMBINED, A Permanent Physical Culture Course for Men, Women, and Children. Health-giving, Vitalizing, Prophylactic, Beautifying. A New System of the Characteristic Essentials of Gymnastic and Indian Yogis Concentration Exercises Combined with Scientific Massage Movements, with 80 Illustrations and Deep Breathing Exercises. By ALBRECHT JENSEN, Formerly in charge of Medical Massage Clinics at Polyclinic Hospital and other Hospitals. New York: Albrecht Jensen, 220 West Forty-second Street, 1920.

THIS book contains very full and clear descriptions of fourteen movement exercises, without apparatus, combined with self massage. The exercises are quite simple and are very easily performed and can be gone through methodically in the course of ten or twenty minutes. The massage movements are more than the mere rubbing of the skin, tapping, stroking and pressing being brought into action. Combined with the movements and massage are certain breathing exercises. Altogether the author presents a system of health culture that cannot fail to benefit all who will take the short time and the slight trouble to master and to practice it.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held May 7, 1920.

DR. SEWARD ERDMAN IN THE CHAIR.

Foreign Body in the Right Lung for Five Years: Removal, Recovery.—Dr. JOHN C. A. GERSTER presented a young man who had been stabbed with a file just below the angle of the right scapula on December 8, 1913, in Portland, Ore. The patient was in a hospital for thirty-seven days and after that was detained in jail for seventy-two days as a witness. Then for four years he worked in the west as a lumberman and finally came to New York, where he was drafted, sent to Camp Upton (308th Inf.), and finally overseas with the 77th Division. On September 8, 1918, he was wounded in the right forearm by a machine gun bullet at the crossing of the Aisne Canal, and later was returned to Fox Hills Hospital, Staten Island. From there he was sent by the War Risk Insurance to the Clinic for Functional Reeducation for the treatment of his incapacitated right forearm. He complained of pain in his right thorax and an *x*-ray taken showed a foreign body embedded in the lung. (The man who did the stabbing said he had pulled the file out, but the *x*-ray proved the contrary). The file fragment lay in the right lung almost impinging upon the diaphragm; in front it almost touched the pericardium. Because of the thoracic pain, cough and expectoration, on October 29, 1918, five years and ten months after the stabbing, an intercostal incision was made in the eighth interspace, under intrapharyngeal anesthesia. The foreign body could be felt higher than where the *x*-ray seemed to indicate it was located consequently the rib above the intercostal incision was resected. This afforded sufficient space so that the hand introduced into the thorax could grasp and rotate the file so that its posterior end covered by lung tissue presented and could be cut down upon, seized, and extracted. A catgut stitch closed the hole in the lung tissue. Layer suture of the thoracic wound was made, with a small drain at the center of the suture line. An empyema developed which was treated by Dakin's solution for eighty-two days, when the wound closed. Since closure of the empyema sinus the patient had had two colds and one attack of influenza. Thoracic pain persisted for some time but had now entirely subsided. The *x*-ray plates showed a distinct halo about the file, three-quarters of an inch away from it. The file was embedded in thick fibrous tissue to which it was densely adherent; no abscess cavity was present. *X*-ray plates taken three months later showed persistence of the halo. The specimen was a three-cornered file 5¾ inches in length. Recent *x*-ray plates which were exhibited showed the lung perfectly aerated. The patient stated he now felt perfectly well.

Dr. EDWARD WALLACE LEE asked Dr. Gerster what the condition of the patient's lung was at the present time; whether there was any consolidation.

Dr. GERSTER replied that there was no evidence of consolidation, although there surely were adhesions as a result of the empyema.

Gastrectomy with Reconstruction of Physiological Rapports Between Stomach and Intestines.—Dr. A. L. SORESI presented this patient, operated upon on March 5, for the purpose of demonstrating the absolutely physiological functional results that were obtained by his method. Dr. Soresi said all the cases operated with his method confirmed his contention that the operation was physiological because they showed the formation of a new antrum pylori. The carcinoma removed in this case was very extensive and about four-fifths of the stomach was removed. The series of *x*-ray plates showed the gradual, almost normal, emptying of the stomach, the emptying time being between three and four hours; this time might be considered normal, given the small size of the stomach. The patient had gained about twenty pounds since the operation, and ate all kinds of food.

Dr. Soresi recommended the following technique for gastrectomy: Complete removal of all adhesions from the field of operation; separation of the omentum from the colon; ligation and division of about 6 cm. of the gastro-colic and gastro-hepatic ligaments around the pylorus; tying the blood vessels as they presented themselves. The duodenum was caught with strong forceps at about one centimeter from the lesion and sutured with special through-and-through stitches at a distance of about 3 mm. from the forceps, it was then severed between the suture and the forceps; the stump of the stomach and the forceps closing it are then covered with gauze, and the stump of the duodenum was inverted with a sero-serous suture. The stump of the stomach is now raised up and the gastro-colic and gastro-hepatic omentum ligated up to the point of the stomach that the surgeon intended to resect, at the same time the posterior surface of the stomach was freed from any adhesions and the blood-vessels were ligated. Strong forceps were placed on healthy tissue of the stomach, and the same stitches used for the duodenum was employed to suture about two-thirds of the stomach at about 3 mm. from the forceps, beginning from the cardiac side, leaving about 4 cm. unsutured; Doyen forceps were placed on the unsutured portion, and the portion of the stomach to be resected was cut away along the forceps. The through-and-through suture was covered with a sero-serous suture. The jejunum was located and severed at about 5 cm. from the Treitz's ligament and the proximal stump covered with gauze and temporarily abandoned. The distal stump was passed through a split in the mesocolon and sutured along side the unsutured portion of the stomach, with a sero-serous suture made with parallel stitches, using two needles; it was then severed longitudinally with an incision of the same length as the unsutured portion of the stomach. A special through-and-through suture then approximated the cut edges of the stomach and the jejunum in such a manner that it resulted in a kind of antrum; the sero-serous suture was then continued all around, half with each needle. Silk was always used for the sero-serous and catgut for the through-and-through suture. The split in the mesocolon was sutured around the jejunum, and the proximal stump of the jejenum was implanted in the distal stump with a termino-lateral anastomosis. The advantages of the method were: The operation was easier because every step was helped by the preceding one, and each was made in the open; there was no danger of hemorrhage, of infecting the operating field, or of injuring important structures, such as the middle colic artery; trauma was reduced to a minimum; the operation was carried on every rapidly and safely, less than an hour in uncomplicated cases; finally, the function of the stomach after the resection was physiologically correct, because the bile and the pancreatic juice did not enter the stomach but followed the physiological route; the anastomosis between the stomach and jejunum was both safe and rational, forming a kind of antrum pylori.

Empyema Treated by Author's Method.—Dr. A. L. SORESI presented five patients from his service at the Greenpoint Hospital for the purpose of demonstrating the results obtained with a new technique which he had devised the principles of which were delayed operation, and negative pressure in the pleural cavity from the beginning, while pus was completely drained out at the same time. Dr. Soresi advised late operation, because he claimed that the pus found in the pleural cavity represented a means of defense of the organism which should not be removed until such defense was not necessary, that was, until the acute symptoms have subsided. The direct treatment must not be uncomfortable for the patient, must drain the pus and favor early progressive expansion of the lung, and must not be the cause of immediate or late complications. Dr. Soresi used local anesthesia, incision between the ninth and tenth ribs, but without rib resection, along the scapular line. The point of the incision must, however, be determined by exploratory aspiration, and must be made where pus could be obtained freely. Drainage of the pus and lung expansion was obtained by the use of a new instrument, which was a cannula composed of two halves which were easily introduced into the pleural cavity, cannot slip in or out, and formed a large oval opening which was

covered with a special valve and a cap. The valve prevented the entrance of air into the pleural cavity and the cup drained the pus into a bottle, so that no dressing was necessary and the patient was never disturbed for any reason, and could rest comfortably and get about very early. The cannula was left in place on an average of from ten to fifteen days. In one case presented it was removed on the seventh day, and the patient left the hospital two days later, that was, nine days after operation. *X*-ray pictures from the patients presented showed conclusively the beautiful results obtained by this method, which has been applied successfully in numerous cases.

Case of Pyloric Ulcer with Symptoms that Might Be Ascribed to an Existing Epigastric Hernia—Pylorectomy.—Dr. LEO B. MEYER presented this patient, a man 60 years of age, as a part of the symposium on gastric and duodenal ulcers, and also because of the statement frequently made that an epigastric hernia associated with gastric ulcer symptoms meant that the hernia was responsible for the gastric symptoms. While this was often true this case proved the necessity of carefully ruling out a definite gastric lesion before assuming an epigastric hernia to be the sole cause of gastric symptoms. This patient was also of special interest in connection with Dr. Lewisohn's statement that it was advisable to exercise an ulcer in view of the frequency with which ulcer recurred and the possibility of its becoming malignant. The patient was admitted to Beth Israel Hospital four weeks previous with an indefinite gastric history. The *x*-ray examination was negative except for a six-hour residue; there was no evidence of a filling defect. The patient had a distinct epigastric hernia. The diagnosis of ulcer was made on the basis of the six-hour residue. This was one of those cases in which an operation for the epigastric hernia would have produced no results. There was an indurated, contracted ulcer on the posterior aspect of the pyloric ring; though there were no enlarged glands or evidence of carcinoma it seemed advisable in view of the man's general appearance and age to remove the ulcer. A resection was therefore performed with a suture posterior gastroenterostomy.

Resection for Carcinoma of the Stomach (Four Years Ago).—Dr. RICHARD LEWISOHN presented this patient, a man 55 years of age, who was admitted to Mount Sinai Hospital on August 15, 1916, complaining of weakness, belching, vomiting and loss of weight. No definite mass could be palpated in the epigastrium. Gastric analysis showed a marked residue, blood, lactic acid, and no hydrochloric acid. *X*-ray examination showed a marked pyloric obstruction. The operation revealed a large carcinoma at the pyloric end of the stomach, with extensive adhesions to the pancreas. The tumor was resected and a button gastroenterostomy performed. The microscopical diagnosis showed it to be a colloid adenocarcinoma. The patient began running irregular temperatures two weeks after the operation and developed an empyema. At that time he was in such a poor condition that we simply drained the pus by an intercostal incision under local anesthesia. He then made an uneventful recovery. He has gained 85 pounds since his operation and was in perfect health. It was well known that cures following a resection of carcinoma of the stomach extending over two years were rare. However, they did occur occasionally. For this reason we ought to be very radical in our operative indications. The size of the tumor and adhesions to surrounding organs were certainly not contraindications. This case was distinctly on the borderline of operability and yet now, nearly four years after operation, this patient was strong enough to daily fulfill his arduous duties as a street car conductor.

Penetrating Ulcer of the Posterior Wall of the Stomach.—Dr. RICHARD LEWISOHN presented this case. He stated that the patient, 23 years of age, was admitted to Mount Sinai Hospital, on March 13, 1920. He had complained for the last five years of epigastric pain, which was relieved by food. There was a distinct periodicity present, there being an absence of symptoms during the summer months. He had been vomiting during the last few weeks previous to his admission. Palpitation revealed an indefinite epigastric tenderness. The *x*-ray showed a penetrating ulcer at the lesser curvature of the stomach, at the junction of the horizontal and vertical portions. The duodenal bulb was somewhat irregular. The operation revealed a penetrating ulcer of the posterior wall of the stomach, densly adherent to the pancreas, which formed the base of the ulcer. The pylorus and duodenum were normal. The irregularity of the bulb shown in the *x*-ray picture was evidently caused by reflex spasm. A number of large, hard glands, surrounding the ulcer and extending upwards on the lesser curvature, suggested the possibility of malignancy. However, preferring to give the patient the benefit of the doubt he performed a subtotal gastrectomy and button gastroenterostomy. The patient made an uneventful recovery. The specimen showed a large crater ulcer about one inch away from the lesser curvature. A careful microscopical examination failed to show any suspicion of malignancy. The *x*-ray picture, although absolutely pathognomonic as to the diagnosis of penetrating ulcer, was rather deceptive as to its situation. The barium meal pulled down the movable part of the stomach and this brought the ulcer, which was adherent to the pancreas, to the top level. It thus gave the impression that the ulcer was situated at the lesser curvature. The ideal procedure for these cases was partial gastrectomy, the local excision in connection with gastroenterostomy gave fair results though the permanent cures were not so frequent as those following gastrectomy. Simple V excisions and sleeve resections for secondary hourglass formation should not be used. A simple gastroenterostomy was an illogical procedure for ulcer of the lesser curvature or posterior wall of the stomach. If removal was impossible a temporary jejunostomy might give very good results. One of the most difficult questions to definitely decide by palpitation was whether the ulcer was benign or malignant. Large glands, as in this case, might be purely inflammatory. It was therefore advisable to give these patients the benefit of the doubt and to perform gastrectomy, if this procedure was technically possible.

Gastrojejunal Ulcer (Two Cases).—Dr. RICHARD LEWISOHN presented these patients. The first patient, he said, was admitted to Mount Sinai Hospital on January 28, 1919. He had been operated on three and one-half years previously for duodenal ulcer. The operation consisted in gastroenterostomy and pyloric exclusion. He was perfectly well up to six weeks ago. Since then he had been suffering from severe pain, belching, and eructations; but no vomiting. The *x*-ray department found that the jejunum for about two inches beyond the stoma was considerably dilated and resembled a small accessory pouch. This pouch emptied rapidly. There was tenderness over the entire gastric area. None of the food was seen going through the pylorus. The stomach was dilated, the peristalsis exaggerated. A considerable residue was present after six hours. The diagnosis of obstruction of the jejunum, probably due to adhesions, was made. Operation, February 1, 1919, revealed a gastrojejunal ulcer at the anterior and left aspects of the stoma. The ulcer was hard and indurated. The site of the exclusion represented a narrow opening only large enough to permit the passage of fluids. In this case the transverse mesocolon was separated from the site of the stoma and the stoma was opened. The ulcer and the indurated area were excised, leaving the posterior suture line intact. The opening was then closed with chromic gut sutures after widening of the stoma by lengthening openings in the stomach and jejunum. In order to force feedings immediately a temporary Senn jejunostomy was performed and a tube inserted. The patient was fed through this tube for thirteen days. The tube was then removed. The opening closed in a few days. The patient left the hospital three weeks after the operation and has been perfectly well since then. The Pagenstecher linen thread had been blamed very frequently for the causation of gastrojejunal ulcers, but Dr. Lewisohn stated that he had never found rests of suture material among his personal eight cases of gastrojejunal ulcers. However, non-absorbably material could undoubtedly cause this trouble. It was therefore wise to use chromic gut for outer and inner suture of a gastroenterostomy. The technical procedure in the removal of gastrojejunal ulcers was very much simplified if, as in this case, the posterior suture

line could be preserved. In cases of large indurated ulcers with extensive invasion of the mesocolon, a temporary jejunostomy was the proper procedure. This method set the stomach at rest for some weeks and would thus cure the ulcer, even though its radical removal was out of the question on account of insurmountable technical difficulties.

The second case was that of a man, 29 years of age, who had had four operations during the last six years. He was operated upon six years ago for epigastric hernia. However, this operation did not relieve his symptoms. He was therefore reoperated in the following year for pyloric ulcer, a gastroenterostomy being performed. Ulcers of the pylorus or duodenum were often overlooked in the presence of an epigastric hernia. Every case of epigastric hernia with stomach symptoms ought to have an *x*-ray taken before the operation if there was the slightest doubt of an intra-abdominal lesion the abdomen ought to be explored thoroughly. The small incision for epigastric hernia ought to be more and more abandoned in favor of thorough exploration, just as we had learned that the small appendicular incision was not the ideal procedure in many cases. This patient was brought to Beth Israel Hospital one year after his second operation suffering from an acute perforation of a pyloric ulcer. Dr. Goodman operated immediately and closed the perforation. It was interesting to note that the ulcer suddenly perforated one year after the performance of a gastroenterostomy. The patient felt fairly well up to about six months ago, when he returned to Beth Israel Hospital with a large ventral hernia and severe epigastric pain. The *x*-ray showed that they were dealing with a gastrojejunal ulcer. The operation which Dr. Lewisohn performed on March 28 consisted of division of extensive adhesions, excision of a gastrojejunal ulcer, and a Mayo herniaplasty. The patient made an uneventful recovery.

Rhinophyma.—Dr. JAMES FRANCIS GRATTAN presented his patient, a man 43 years of age, who dated the initial change in the tip of his nose to his tenth year, when the end of his nose was severely lacerated by a dog bite. At the age of 11 or 12 years he had a facial erysipelas, and during his youth received several bad blows and falls involving his nose. Two and a half years before coming under the speaker's observation he had had a second attack of erysipelas. There was a globular tumor on the tip of his nose about 1¼ inches in diameter, almost a perfect sphere with a base almost as broad as the diameter of the mass and extending upward on the anterior surface to the junction of the middle and lower thirds of the nose, and laterally to the alæ nasi. Chronic acneform lesions dotted the skin over the entire tumor. The operation was as follows: A U-shaped flap was made above, beginning at each alæ and including about one-half inch of the skin on the superior surface of the tumor mass. An inverted U-shaped was made on the inferior surface of the nose, including the skin of the entire inferior surface of the tumor. The ends of the two U-shaped incisions were made to meet at each alar crease. The flaps thus outlined were dissected off the tumor, and the tumor dissected in a wedge-shaped manner from the underlying nasal cartilage. There was considerable fibrous tissue in the tumor and no distinct differentiation between the tumor and nasal structure. The dissection was rather difficult on account of the conditions. The lower flap was rolled up over the edge of the nose so that the suture line ran directly across the anterior surface of the nose from ala to ala. The upper flap was very difficult to adapt to the new contour, as it had stood out at right angles to the anterior nasal line during the long period that it had covered the upper surface of the tumor. The adaptation was begun by fastening it at its center to the center of the lower flap and then adapting the sides by trimming and scoring the edge, fitting and refitting until the best approximation was obtained. In this way a rather well-shaped nose was moulded out of very discouraging material. Interrupted sutures of fine silk were used. The tension was relieved by sterile adhesive straps. The wound healed by primary union and the patient left the hospital on the tenth day. Aside from the slight redness and the prominence of the sebaceous gland orifices the nose had the appearance of a normal organ. The problem of improving the condition of the skin was discussed with Dr. Fred Wise, who suggested the use of 50 per cent. trichloracetic acid, applied periodically, until the higher prominences of the skin were leveled. The treatment was repeated until all the areas of the nose had been smoothed out, and the result was most satisfactory. Four applications were made in all. Subsequently exposures to the roëntgen ray at three week intervals were given with the idea of further improving the condition of the skin and keeping in abeyance any tendency to recurrence of growth in the tissue treated. This case, Dr. Grattan said, demonstrated the desirability of attempting something for the improvement of conditions of this type. It was impossible to estimate the good effect of the result on the patient's mentality and outlook on life, to say nothing of the physical betterment.

Dr. STEWART ERDMAN asked Dr. Grattan if it was not unusual to find a rhinophyma so distinctly pedunculated as this one, and whether it would be possible to apply his method of operation to a growth more generally disseminated.

Dr. GRATTAN replied that if the enlargement was more general it might be necessary to do a sectional resection, and that would probably not be as easy as this had been.

The Results of Operation on Gastric and Duodenal Ulcers.—Dr. GEORGE WOOLSEY presented this contribution which was based upon 109 cases operated on mostly during the last five or six years, up to December, 1919. This did not include perforated ulcers. Seventy-nine of these operations had been done since January, 1916, at which time the follow-up system was inaugurated on the 2nd Surgical Division of Bellevue Hospital, and late records have been obtained in 75 of these cases. Those who had no gastric symptoms were classed as excellent; those having occasional vague symptoms, not those of ulcer, were classed as satisfactory; while the remaining class of unsatisfactory results included those who complained of a considerable amount of discomfort. Naturally the largest group was that of duodenal ulcer, 58 cases. Of these two died after operation, one of pulmonary embolism and one of heat prostration. Records of 45 of the remainder showed that the immediate results were excellent in 75 per cent.; satisfactory in 15.9 per cent., and unsatisfactory in 9 per cent. The later results were satisfactory in 64.4 per cent.; satisfactory in 26.6 per cent., and unsatisfactory in 8.8 per cent. Combining the excellent and satisfactory results it was found that they had what might be called good results in over 90 per cent. of the cases. In a series of 20 cases of duodenal ulcer, the writer employed pyloric exclusion by a strip of fascia from the rectus sheath, according to the Wilm's method in addition to gastro-jejunostomy. Later he discontinued it thinking it made no difference and added to the time of the operation. He found, however, that the cases with exclusion gave the best results as shown by the figures in this group. Suspicion of a simultaneous chronic appendicitis led to the removal of the appendix in 16 out of 48 cases. Appendectomy at the same time with gastro-jejunostomy did not appear to favorably influence the final results in the patients so treated in this series. In one case symptoms of ulcer recurred twenty-one months after operation and all forms of diet and treatment had no effect. At operation two years after the first operation, about three inches of silk or linen thread was found hanging from the inside of the anastomosis. There was no jejunal ulcer. Since that time he had used no non-absorbable sutures; they were probably the commonest cause of jejunal ulcer. In the group of gastric ulcer treated by gastroenterostomy he had included all that he had private records of, going back to 1902, as the group would be otherwise too small. There were 18 cases in this group, with no post-operative deaths, making a mortality of 2.6 per cent. for all cases of peptic ulcer for which a gastroenterostomy was done. Several of these cases showed that at least some chronic gastric ulcers could be treated by gastroenterostomy alone. In several cases a retrocolic anterior gastroenterostomy was performed, mostly for carcinoma, and had always given satisfactory results. In this series of gastric ulcer treated by gastroenterostomy, the late results were known in 14, being ex-

cellent in 8 and satisfactory in 3, making 78.5 per cent. good results. In the few more or less recent cases of this group the ulcer was situated at or close to the pylorus, and in five cases a pyloric exclusion was done, proximal to the ulcer, to encourage its healing but without affecting the final results very favorably. He was inclined to think that most of these later cases the results would have been better if resection had been done by the Polya-Reichel method. The best results obtained by gastroenterostomy in the gastric ulcer group had been in chronic pyloric stenosis with dilatation of the stomach. Seven gastric ulcers were treated by excision. The writer felt convinced that excision alone was a poor operation for gastric ulcer. It seemed to interfere with gastric motility and did not relieve hyperacidity. Combined with gastroenterostomy, excision, or better perhaps the Balfour cautery operation, might give good results. Excision came into competition with mesogastric resection, but though the postoperative course of the latter had been very smooth the final results had not been so good, so that his early enthusiasm for this operation had somewhat diminished. In the group of gastric ulcers treated by resection of the stomach there were 26 cases of which four died, a mortality of 15.3 per cent. The Billroth 11 method was used in these four fatal cases; they were, however, poor operative risks. Of the remaining 22 cases, 15 had reported the late results. Of these, five gave an excellent end result, seven a satisfactory result, and three were unsatisfactory, making 60 per cent. of good results. One of these cases was later operated on with good results, increasing the percentage of good results to 86.6 per cent. In gastric ulcers situated at or near the pyloric end Dr. Woolsey said he did resection, preferably by the Polya-Reichel technique. If the antrum was normal and the ulcer was three to four inches or more proximal to the pylorus he had done as mesogastric resection. Where the ulcer was so far from the pylorus as to make this operation quite difficult, an excision or the Balfour-cautery method, with a gastroenterostomy was preferable. This group included eight mesogastric resections with no death. At first he was strongly in favor of this method, which had the advantage of not requiring a gastroenterostomy, but he had been disappointed with its results. The satisfactory results comprised only 60 per cent. Many of these cases presented the worst type of chronic ulcer in unpromising specimens of humanity. Five out of the eight were situated posteriorly, adherent to, and sometimes penetrating the pancreas. Excision and cautery was not suitable in these cases and a complete resection involved the removal of a large segment of the stomach. In such cases adherent posteriorly, he believed the mesogastric resection was indicated. Four cases operated on by the Billroth 11 method, and two of the cases gave good results, one satisfactory, and one excellent. It was a striking fact that in the four cases of gastric ulcer in which this method was employed, on account of adhesions posteriorly, the end results had been excellent in all in which it was known. The Polya-Reichel method was used in nine cases with 100 per cent. of good results. This operation had given much satisfaction. It saved time as compared with the Billroth 11 method, and, according to the voluntary testimony of the house staff the postoperative convalescence was smoother and more satisfactory. In the majority of the 109 cases (71.5 per cent.) the ulcer had not been removed or cured by the operation. The latter merely put the stomach in such a condition mechanically and chemically, that the healing of the ulcer was favored. In addition, then, these patients should have a dietetic cure and the postoperative period offered ideal conditions for this régime. In a given case of gastric or duodenal ulcer one could not guarantee a good result from operation, but one could assure such patients that in a very large percentage of cases, 85 to over 90, suitable operation offered good results, both immediate and lasting. This held good where medical cures had been tried and failed.

Fluoroscopic Diagnosis of Duodenal Ulcer.—Dr. ARTHUR L. HOLLAND presented this contribution in which he said that the statement that duodenal or postpyloric ulcer could be diagnosed or excluded by any method or combination of methods in 90 per cent. of the cases sounded extravagant. That this was possible they had demonstrated in the New York Hospital, and further they had demonstrated that by the fluoroscope alone, disregarding the findings of the history, gastric analysis, feces analysis, and physical examination, they could in 90 per cent. of the cases and more accomplish this end. This percentage had been practically duplicated in the Cornell Surgical Division at Bellevue Hospital. In 52 cases diagnosed duodenal ulcer at the New York Hospital and Cornell Clinic and in private practice, 47 had been confirmed at operation. In the remaining five cases no lesion of the duodenum was observed at the operation, but in most of these cases there were extragastric lesions, such as adhesions, gallbladder disease or chronic appendicitis, no doubt causing some spasm of the cap which had been mistaken for evidence of ulcer. In 38 cases operated for other conditions, in which a negative diagnosis for duodenal ulcer had been made flouroscopically by them, in one instance only was an ulcer found, and this was a very small apparently healed affair. The object of the paper was to emphasize the importance of the flouroscope in this field and to suggest a technic for making observations and interpreting the findings. The observer should not approach the case prejudiced by a knowledge of the history, physical examination, or laboratory findings. He should protect himself with heavy lead-impregnated rubber gloves, as it was impossible to use the fluoroscope to advantage without considerable manipulation of the abdomen. Unless one became proficient in the art of manipulation and fearlessly proceeded he had much better rely on plates. Wooden spoons and other substitutes for the hands were clumsy and inefficient. The time of actual exposure of a patient during one week should not be over twenty minutes to one-half hour. The usual five inch gap and five milliampères were employed. The patient required no special preparation except that the meal previous to the observation be omitted. If the patient was habitually constipated the usual laxative might be given, but strong cathartics such as castor oil were contraindicated as a false impression of the motility of the tract was apt to result. The patient should always be examined in the vertical position. It was essential that the opaque meal should be of heavy gravity and much more thoroughly mixed than usual. The most satisfactory mixture was one of eight ounces of barium sulphate, one-half ounce of sweetened condensed milk and twelve ounces of water. Buttermilk was not satisfactory as a menstrum as the resulting shadows were not uniform and clear-cut. After quickly scanning the shadows of the heart and lungs, the patient was placed in the right anterior oblique position and the shadow of the meal passing through the esophagus was watched for evidences of stricture, spasm, or dilatation. The mode of entrance into the stomach was noted, as the patient was again turned to the antero-posterior position, also the course the meal took to the lower part of the stomach. When the stomach was full a diagnosis of the shape, size, position and tone was made at once. The patient should be observed both antero-posteriorly and in the right anterior oblique position. In about 50 per cent. of cases a spasm of the antrum was an early occurrence, but as the temperature of the meal was brought to that of the stomach this subsided in a few minutes except in the cases in which the spasm was secondary to some pathology further along in the tract or in adjacent organs. After allowing for the proper filling of the antrum and going over the outline of the stomach from all angles the examination could be discontinued for five or ten minutes. On resuming the enamination, if the antrum had not filled pressure at the fundus would usually accomplish this end. If when filled it presented a clear-cut shadow of triangular shape, or rather the Indian arrow-head shape, and viewed from all possible angles retained this shape, one could be quite sure that there was no pathology present in that part. Of the difficulties in these observations, the shadows in the descending duodenum obscuring a clear view of the cap were the most troublesome. These were overcome by the observer holding aside through the abdominal wall the descending duodenum. It was here that the fluoroscopist scored an advantage over the radiographer. Where there was incomplete spasm of the cap, the opaque meal might spurt through without distending the bulb and and filling the descending

duodenum, leaving a gap between the antrum and the descending portion. Hasty opinion should not be given because of this, but a persistent effort made to fill out the bulb by pressure. A small ulcer might give the shadow the appearance of a large filling defect and *vice versa*. If one found a clear-cut filling defect that did not show some little change from time to time one could be fairly sure that the ulcer was not active and was probably a healed affair. In the writer's experience, filling defects occurred most frequently on the greater curvature surface of the cap near the pyloric interval, or base of the cap. The next most frequent site was on the lesser curvature of the cap somewhat near its apex; a combination of these two types frequently occurred. Healed prepyloric ulcers causing partial obstruction were better treated surgically than medically, as sooner or later complete obstruction usually took place. On the other hand, the definite, clean-cut filling defect on either curvature of the cap, without very marked deformity, was a medical problem until frequent recurrences made surgery more attractive and less expensive. In addition to the diagnosis of post-pyloric ulcer in this region there were other things to consider. Adhesions or pressure from without might distort the outline of a perfectly normal cap. Then, too, there were folds on the greater curvature of the surface of the cap that were very similar to the defects of an ulcer. The essayist described how these were to be differentiated by pressure properly applied by the observer. A cap that was too freely movable, and this did sometimes happen, might become distorted through its own weight, but this could also be filled out by pressure applied from below. A small cap might tell of obstruction at the pylorus. On the other hand, an unusually large cap might be due to obstruction beyond the cap, particularly at the junction of the descending and transverse duodenum where a kinking might cause back-tracking. Dilatation of the right side of the cap under the fluoroscope where operation had been performed had demonstrated some pathology on the left side or posterior surface of the bulb, the dilatation simply being a compensatory process. One frequently heard of clinicians and surgeons who had abandoned the use of the *x*-ray in gastrointestinal work, arguing that ulcer at least could be diagnosed by ordinary clinical methods in a large percentage of cases, but they all knew that there was an irregular type of the disease that knew no laws and that these were frequently the most dangerous and too often made emergency surgery necessary. Furthermore clinical methods did not place the lesion, and this to the surgeon was most important. Still further there was always the danger of cancer supervening in gastric ulcer, while this danger was not present in post-pyloric ulcers, so that diagnosis as to location was most essential. One could also tell quite accurately by the fluoroscope whether duodenal ulcer was responding to medical treatment. Dr. Holland also described a method that they had employed in a few selected cases that were difficult to observe because of persistent pylorospasm or spasm of the cap itself. This consisted in passing a duodenal tube into the duodenum and introducing through it a small quantity of opaque meals. In this way they could see not only the cap, but the descending and transverse duodenum permitting their relations to be studied to much better advantage.

Dr. JOHN F. ERDMANN said that he spoke purely from the surgical standpoint. In regard to the presentation of the patients he was particularly impressed by the fact that surgeons were getting more revision operations. He had had three patients come back upon whom he had operated himself and a number upon whom others had operated. He had come to the conclusion that certain people had the habit of reproducing ulcers and he thought that a status of this type should be taken more into consideration. He had had patients in whom he had had to operate two, three, or four times in the course of five, six or seven years. The recurrence of ulcers in this way seemed to be a habit or thus something was wrong with the diet. The type of operation did not seem to make any difference as to the recurrence. Some of these patients were kept under observation on simple diet and this did not seem to prevent recurrences. Patients with recurrence usually complained of pain in the hypochondrium and lumbar region. In reference to ulcers in the pyloric zone, exclusion of the pylorus had never been satisfactory in his hands. For six or seven years he had been devoted to excision of the ulcer, but now he did an excision and a gastroenterostomy in addition, if demanded. Dr. Erdmann expressed himself as much gratified and pleased to hear Dr. Holland's paper because he had been rather skeptical of the fluoroscopic diagnosis. Dr. Holland is to be congratulated on his high degree of diagnostic ability with the fluoroscope.

DR. JOHN ROGERS said that Dr. Erdmann's remarks about the post-operative recurrence of gastric ulcer prompted him to some reflections upon the origin of the disease. In the great majority, if not in all, of the cases it occurred in "nervous" subjects. That was, in people who by their responsiveness to environmental influences were peculiarly subject to fatigue. They reacted to nervous or mental, as well as purely physical stimuli, with more than the usual vigor, and hence were peculiarly subject to fatigue. This always affected first the nerve terminals and thus impaired their function. In the stomach, the vagus apparently activated, or "drove," this organ, while the sympathetic inhibited or "checked" it. If the functions of the involuntary nerves were at least partly "trophic," then suspension or interference with this function as the result of fatigue should lead to "trophic" disturbances and ulcer could develop wherever the circulation was most impaired. It was certain that the most constant element in the clinical history of these cases was a so-called "nervous" fatigue. This meant a psychological activity which involved mental inhibition. There always seemed to be a simultaneous visceral inhibition which was exerted through the sympathetic or "check" nerves. If the latter became fatigued, as there was every reason to believe they would, all the subjective symptoms of gastric ulcer appeared and could be avoided only by the relief of the fatigue or by mental and physical rest.

DR. EUGENE H. POOL said he had not intended to enter into the discussion, but a word was due from some one on the staff of the New York Hospital in regard to Dr. Holland's paper. He had followed the work from the start, and though in the beginning he was very skeptical he had been carried away by the results Dr. Holland was getting. He felt convinced that Dr. Holland had understated rather than overstated his claims for the flouroscope. If it came to a question of giving up *x*-ray plates or the fluoroscope it would be safer to give up the plates. An important feature of the flouroscopic examination was the way in which a man who had had as much experience as Dr. Holland when the bismuth meal was in the stomach could manipulate it and press it up against the pylorus, and then empty the pylorus, and by these manipulations could demonstrate any filling defect that might be present. In this way he had not only demonstrated ulcer but also a diverticulum on one occasion. Dr. Holland's findings had been almost uniformly demonstrated at operation, so he felt that in his modesty, Dr. Holland had understated his figures.

DR FENTON B. TURCK brought out the point that the fact that cases of gastric and duodenal ulcer failed to recover under both medical and surgical treatment emphasized the necessity of a further study of the etiology of ulcer, not only for the sake of finding the cause of ulcer but of determining what happened as a result of these broken down cells in the body. In his feeding experiments in animals both pyloric and prepyloric ulcers had been produced in various ways reported in the literature, but the most significant thing was that he had been able to produce ulcers by the injection of burnt tissue. These ulcers were not produced merely because the tissue was burnt but because it was dead tissue; if one simply allowed tissue to autolyse and then injected it the same results would ensue. There were various methods of causing tissue necrosis, and one method was by deficiency feeding from which there resulted a breaking down of the animal's own tissue which produced the same results as the injection of necrosed tissue. The reason ulcer occurred more often in the pyloric region and in the duodenum was because there was more erypsin in these localities and hence a more rapid breaking down of tissues. Reactions from burns occurred more often in the upper than in the lower in-

testinal tract and the same was true of shock. By adding extracts of beef and the ordinary intestinal flora which interfered with the proper utilization of food elements a breaking down of the animal's own tissue occurred. Ivy had recently reported similar experiments in the *Archives of Internal Medicine* (January 15, 1920) in which he had obtained precisely the same results. Stewart and West (*Jour. of Immunology*) attributed the formation of ulcers in Dr. Turck's experiments to acidosis, but acidosis he had shown was a result and not a cause. It was well known that after perforation of ulcers, there were seldom recurrences, and this was explained on the ground of the perforation resulting in autovaccination and the production of antibodies, and finally, immunity. In this same way Dr. Turck said he had produced immunity in animals by injecting autolyzed tissue into a horse, and at the end of the year had produced a serum which would produce immunity to ulcer in animals. A serum made with human antigen had been used in the cure of peptic ulcer in patients. Recurring ulcers after operation and cases of ulcer not operated on, had been cured as demonstrated by *x*-ray and the disappearance of all symptoms. He recommended such a procedure for the purpose of preventing the recurrence of ulcer in human beings.

DR. WOOLSEY, in closing the discussion, said that gastrojejunal ulcer was often a very difficult proposition when it came to operation, but he had seen relatively few ulcers of this type. In that connection he thought the Roux operation had rather an unsavory reputation, and Dr. Soresi's operation appeared from the diagrams to be similar to it. As he looked at it one of the objectionable characteristics of this operation was the segment of jejunum leading from the stomach to the point at which the duodenal contents entered it and neutralized the acid chyme. However, the problem of jejunal ulcer was much less serious since the use of non-absorbable sutures had been abandoned or else only interrupted silk sutures used. He thought most jejunal ulcers were due to non-absorbable sutures. Dr. Woolsey also added his testimony to the efficiency of the very beautiful results obtained by Dr. Holland in his fluoroscopic work. He had watched Dr. Holland fluoroscope a good many cases previous to being operated on by him at Bellevue and operation had always confirmed the findings.

SECTION ON MEDICINE.

Stated Meeting, Held May 18, 1920.

DR. CARY EGGLESTON IN THE CHAIR.

THE program of the evening was contributed by the Second Medical Division (Cornell) of Bellevue Hospital. **Bronchial Asthma: Response to Pilocarpine and Adrenalin.**—Dr. HARRY L. ALEXANDER and Dr. ROYCE PADDOCK made this presentation by invitation. They stated that the apparent causes and factors responsible for bronchial asthma varied widely among different individuals. The paroxysm itself seemed to be the one factor relevant to the condition that was common to all. During the past winter a series of twenty patients with bronchial asthma was studied in detail with the hope of correlating the symptoms and signs which all, or nearly all, might present. From these patients careful histories were obtained, physical examinations made with reference to lesions of the nose and throat, signs of vagotonia, status lymphaticus, cutaneous reactions to foreign proteins, *x*-ray of the chest, and, when indicated, of the paranasal sinuses and the intestinal tract, blood counts, sputum examinations, response to pilocarpine and epinephrin. Although most cases showed emphysema as well as abnormal nasal conditions, and many an eosinophilia in the blood and sputum, a low systolic pressure and increased lung markings in the *x*-ray plates, the outstanding feature was the increased sensitiveness to pilocarpine. Pilocarpine evoked a response in organs innervated by certain branches of the vagus as well as in the sweat glands, the salivary glands, and in the vasodilators of the head, which many authors thought belonged to the "extended vagus" or automatic system. Stimulation by adequate doses of pilocarpine, therefore, might lead to salivation, sweating, flushing, moisture of the eyes, and asthma, for the circular musculature of the bronchioles was also innervated by the vagus. Most investigators recommended 0.01 mg., or about 1/6 gr. of the drug to bring out these reactions, but as this dose evidently gave a marked response in many apparently normal individuals, the writers deemed it wiser to use smaller doses, and in this series 0.003 mg. or 1/20 of a grain, was employed. To this normal people gave very scant or no response, whereas vagotonic patients, with or without asthma, gave varying degrees of reaction which appeared within twenty minutes. In this series the asthmatic attacks and the incidence of these signs, as compared with those in the control series, was of such frequency as to support the contention that a large proportion of these cases might be considered as vagotonic. In this series of 20 cases positive adrenalin reactions were obtained in 13 cases, some of the most pronounced reactions occurring in those who gave the most marked reactions to pilocarpine also, and who presented other distinct evidence of vagotonia. Charts were shown demonstrating the response to adrenalin in an apparently normal individual, the dose being 0.5 c.c. adrenalin chloride solution 1/1000 subcutaneously; in some cases of bronchial asthma with low blood pressure, and in some with normal blood pressure. Physical examination revealed no evidence of hyperthyroidism in these individuals. An analysis of the series showed an interesting relation between the adrenalin response and blood pressures, namely, that adrenalin response occurred only when the blood pressure was low, while no reaction occurred when the blood pressure was approximately normal. In those patients with low blood pressure and bronchial asthma obviously the two factors, bronchial constriction and peripheral vasodilatation occurred. It was an interesting observation that in many of these patients very small amounts of adrenalin sufficed to relieve asthmatic paroxysms, as contrasted to the asthmatic patients with normal blood pressure, who gave no adrenalin response; in the latter group it required larger doses to attain the same results. Similarly, the sensitive cases reacted to the drug tests where 0.5 c.c. of adrenalin chloride 1/1000 was employed with distinctly unpleasant symptoms and often with exorbitant rises of blood pressure and pulse, whereas these symptoms were absent in the latter group. It was obvious that the habitually larger therapeutic dose of this powerful drug, as used in bronchial asthma, might be greatly in excess of the requirement. Caution was therefore urged against the promiscuous use of adrenalin in asthma. Their results were not in accord with the work of Eppinger and Hess and of Frank, who claimed that in bronchial asthma epinephrin had little effect on blood pressure. It was suggested that in subjects with bronchial asthma who were sensitive to adrenalin, the increased vagus tone might be merely relative, due to epinephrin insufficiency. It might be reasonably assumed that an excessive reaction to adrenalin ought not invariably to be interpreted as due to an increased tonus of the true sympathetic system. The writers stated that this study by no means implied disregard for many successful measures employed in the treatment of bronchial asthma, such as specific protein therapy, attention to nasal conditions and other rational methods.

Dr. ROBERT A. COOKE said it seemed to him the chief interest in this work lay in the fact that it demonstrated that bronchial asthma was merely the outward clinical expression of a widespread constitutional defect. The asthmatic individual had bronchial asthma as the chief clinical manifestation, but in over 50 per cent. of the cases a careful clinical history would disclose some other form of hypersensitiveness, such as urticaria, angioneurotic edema, or vasomotor rhinitis. And further, as had also been brought out in the paper, these people were subject clinically to a great many different forms of vasomotor disturbance, such as fainting, blushing, hyperidrosis, and other manifestations of vagotonia. It was a very interesting fact that such a large percentage responded not only to pilocarpine, but reacted to adrenalin as well. It seemed that in Dr. Alexander's series something like two-thirds responded to pilocarpine and at the same time gave an adrenalin response. This, it seemed to him, indicated

an irritability of the autonomic nervous system. Dr. Cooke said that personally he had not made many observations of this sort, but in a few instances he had found that these cases of bronchial asthma responded not only to pilocarpine and adrenalin, but also to atropine. The symptoms of overdosage with an allergen were those of vagotonia and sympatheticotonia, and indicated that they were dealing with a vagotonia, and a sympatheticotonia, in other words, with an abnormal irritability of the entire autonomic system. In such individuals it was an interesting question whether there was any causal relation between their vagotonia and protein hypersensitiveness or whether this was simply a concomitant condition, or whether as a result of their repeated hypersensitive reactions to certain proteins they had developed this irritability of the entire autonomic system. He did not think this question could be answered to-day, but the result of observations made thus far suggested that these individuals who had hypersensitive reactions over a long period developed a nervous mechanism that was rendered extremely irritable to all substances that acted upon the automnomic system.

A Study of the Metabolism and Heat Regulation in Pulmonary Tuberculosis.—WILLIAM S. MCCANN and DAVID P. BARR contributed this paper, in which they stated that in 1908 Prof. Irving Fisher presented data before the Sixth International Congress regarding the dietary given tuberculous patients of ninety-five of the leading sanatoria of the world, showing a wide divergence of opinion as to the food requirements of such patients. The average daliy calories fed varies from 5500 to 2140. The proportion of calories from protein varied from 10 to 25 per cent of the total calories. From the summary of the data Professor Fisher concluded that forced feeding should be abandoned and that the proportion of nitrogenous food should be reduced. With this opinion clinicians had shown an increasing tendency to agree. Dr. Fisher himself had said that no science ever made progress which centered on opinion. The only tribunal in true science was the tribunal of facts, carefully arranged and sifted. With this need of facts the present work was undertaken. After referring to the methods of others in determining the toxic destruction of protein in tuberculosis the writers stated that they had determined the "wear and tear" quota of nitrogen, or the minimum to which the protein metabolism might be reduced by the reduction of the nitrogen intake at the same time maintaining sufficient nonprotein calories. In this way it appeared that the protein metabolism could not be reduced to the same low level in the tuberculous as had been observed in normal men by Thomas, Siven, and Chittenden. In comparison with similar experiments made in typhoid fever by Kocher it appeared that the wear and tear quota was somewhat less in tuberculosis, and that a low level of protein metabolism might be attained at the expense of much less carbohydrate. Loss of nitrogen in the sputum must also be taken into consideration, and since this existed for the most part in the cellular elements of the sputum, it would bear about the same relation to nitrogen balance as nitrogen lost in the hair, nails, and epidermis. The material upon which this study was based consisted of 14 tuberculous patients upon whom 26 observations were made, which varied in duration from one to four hours in the Russell Sage calorimeter, using the methods of direct and indirect calorimetry. Charts were presented showing the detail of the work. In additions to the estimations of the toxic destruction of protein and the observations on heat production, in two cases the specific dynamic action of protein was observed, and in both cases the behavior had differed in no way from that of the normals they had studied so far on the same protein-containing meal. This work showed briefly that the basal heat production of the cases studied had been found not markedly increased. The evidence adduced showed that the protein metabolism might be kept at a fairly low level. Hence from the practical standpoint it appeared that the super-alimentation of bygone days was entirely unnecessary, if not harmful, and that patients might be well nourished on diets relatively low in protein with a very moderate excess of nonprotein calories above the basal requirements of the patient.

Dr. WARFIELD T. LONGCOPE said that he had not had an opportunity to study carefully the feeding in cases of tuberculosis, but that he was familiar and sympathetic with the recent tendency to reduce the forced feeding which was considered, previously, absolutely essential in the treatment of tuberculosis. Though the tendency was to reduce the number of calories in food for tuberculous patients, the exact reason for this had not previously been accurately determined. The studies which Dr. McCann had presented here were of the greatest value in determining the exact caloric needs in chronic tuberculosis, and it could only be through such observations that rational dietaries could be formulated for these patients. These studies immediately suggested the value of similar determination in other types of chronic and subacute infections and through such painstaking investigation it would be possible to determine the proper proportion of food and total calories to be administered to other types of infection. The earlier work on the feeding of typhoid had shown that the progress of this disease could be materially changed by a proper dietary and the same thing was undoubtedly true of such prolonged infections as chronic purulent pleurisy and some types of subacute local infections.

Dr. ORRIN S. WIGHTMAN said he did not know when he had heard a more scientific discussion of the protein bases and of nitrogen balance than the one just presented. There was, however, another factor to be taken into consideration and that was the mineral waste. He had been informed that as a result of what they had learned during the war the French were trying to replace calcium lost from the tissues. He had received calcium and magnesium in ampoules for intravenous injection. It did seem that the calcium and magnesium had a fixed value in bodily metabolism. The calcium need merely supplied the fuel, but did not give any anchorage or control in the bodily economy. In other words, the bodily need was not confined to protein and carbohydrate, but must take into consideration the mineral constituents of the body.

Dr. H. O. MOSENTHAL asked whether any attempt was made to determine whether the fats or the carbohydrates were more efficacious in sparing the nitrogen.

Dr. MCCANN, in closing the discussion, said that in regard to the mineral requirements he had no data whatever. He would suggest, however, that if these patients were getting the required number of calories in a well-balanced diet the mineral constituents would be well taken care of. In reply to Dr. Mosenthal's question, he had no data as to which was the more efficacious as a protein sparer, fat or carbohydrate.

Disorders of the Respiratory Function in Cardiac Disease.—Drs. JOHN W. PETERS, JR., and DAVID P. BARR made this presentation, consisting of a study of the causes of dyspnea in cardiac decompensation, particularly with respect to those defects in the respiratory system that might be termed mechanical, namely, the defects in the lungs and their effect on the discharge of carbon dioxide, with special reference to the low alveolar carbon dioxide tension. It had long been recognized that the alveolar carbon dioxide was usually low in cardiac dyspnea; but the degree of this reduction and its meaning had remained doubtful, and some suspicion was entertained as to the value of the methods employed for the determination of the alveolar carbon dioxide. In 1917 one of the writers had studied this phenomena by the coincident use of the Fridericia method for the determination of the alveolar carbon dioxide and the Van Slyke method for the determination of the plasma bicarbonate. It was found that the alveolar carbon dioxide was always much lower than one would have suspected from the carbon dioxide combining power of the plasma. In the normal person at rest these bore a definite relation to one another, since carbon dioxide output, arterial and venous carbon dioxide tension, and arterial and venous carbon dioxide content varied within narrow limits. In cardiac dyspnea most of these relations were suspected or known to be disturbed. The first object of their studies was to find out whether the normal relations of dead space (the nose, mouth, pharynx, larynx, trachea, and bronchi) and alveolar air existed in cardiacs, and whether samples obtained by the Haldane method represented the effective respiratory air. If they did and

the carbon dioxide concentration in this air was low, it was obvious that in order to effect the same carbon dioxide elimination, the cardiac must exchange a larger total volume of this air than the normal did. This meant that his respiratory mechanism must be less efficient as a means of excreting carbon dioxide. The Haldane method had found little clinical application because of a popular feeling that it was difficult to eliminate subjective errors and that it was only reliable when applied to highly trained subjects. After considerable work with this method the writers had come to the conclusion that the observer needed more training than the subject, and patients with cardiac dyspnea proved no exception to this rule. After having established to their own satisfaction that the Haldane method gave consistently low alveolar carbon-dioxide values in cardiac dyspnea, they next tried to find out whether the samples so obtained were samples of the true alveolar or effective respiratory air. Slides were shown in which the graphic records were arranged according to the magnitude of the expiration, with the corresponding carbon dioxide opposite each. It was evident that in no case did the expirations and carbon dioxide bear any definite relation to one another. It had been shown by Haldane and others that when a person rebreathed air the alveolar carbon-dioxide tension and the ventilation increased as the carbon dioxide in the inspired air rose. When the alveolar carbon dioxide had risen to a certain extent the carbon-dioxide accumulation in the blood became so great that the patient became extremely dyspneic and uncomfortable. If the alveolar carbon dioxide was low in cardiac dyspnea at rest it seemed reasonable to suppose that it should also be relatively low after rebreathing to the point of intolerance. Their observations confirmed this supposition. The results showed that normal persons and compensated cardiacs who had normal alveolar carbon dioxide at rest tolerated an increase to 7 or 8 per cent. The cardiacs with dyspnea, on the other hand, did not rise above 5 to 7 per cent. The height of the alveolar air after rebreathing bore a rough relation to the height of the resting alveolar carbon dioxide. This seemed additional evidence that the low carbon dioxide observed was correct and represented the true carbon dioxide tension of the effective respiratory air. They had employed one other indirect method of approach. According to Haldane and Henderson, the dead space might be calculated in the normal resting person from the carbon dioxide output, the volume of each respiration, and the alveolar carbon dioxide. They had applied this formula to a number of subjects, employing the observed alveolar carbon dioxide and the carbon dioxide calculated from the combining power of the plasma. This also forced them to the conclusion that the alveolar carbon-dioxide tension determined by the Haldane method must be essentially correct. They were led to the further conclusions that this effective respiratory air was entirely comparable, from the functional standpoint, to the alveolar air of normal persons. Such a reduction of the alveolar carbon dioxide demanded an increase in the pulmonary ventilation to effect the normal carbon dioxide output. Any increase in carbon-dioxide production would demand a relatively greater increase in ventilation. They had purposely avoided any mention of the relation of alveolar carbon dioxide tension because parallel studies which they had pursued indicated that it was an entirely different problem.

Dr. WILLIAM S. STADIE said that Dr. Peters had presented some very interesting aspects of respiration in cardiacs. Of particular interest was his conclusion in regard to dead space. Different views had been held on that subject. He reviewed those of Haldane and Henderson and of Pearce, who had shown that the dead space remained fairly constant so that one need only study the total ventilation without making dead space determinations in cardiacs and pneumonias. He was particularly interested in the response cardiac patients made to the increased carbon dioxide content and in the finding that these patients could not stand as high a percentage of carbon dioxide as normal individuals without becoming uncomfortable and dyspneic. He had found that 3½ to 4 per cent. of carbon dioxide was sufficient to cause discomfort in this class of patients. It was important to correlate physical findings with the respiratory exchange. For example, in pneumonia, the inability of the oxygen to reach the blood was quite directly related to the "wetness," so to speak, of the lungs. One could predict the extent of cyanosis or râles on the basis of the alveolar carbon dioxide, or, conversely, on the basis of diminished breathing and cyanosis, one might predict with considerable accuracy the amount of carbon dioxide in the alveolar air.

Dr. PETERS, in closing the discussion, said that the assumption of a constant dead space, as suggested by Pearce, could be made a basis for conclusions only in a large number of individuals, in whom it fell within certain limits on the average. They had tried to correlate the total ventilation to the carbon dioxide in the inspired air. It seemed to them the total ventilation was not a proper measure of the alveolar ventilation in these cases because there was frequently an increase in rate with little increase in tidal air. The presence of signs in the lungs was not necessary for the production of a discrepancy between the alkaline reserve in the blood and the carbon dioxide tension of the alveolar air.

Experiments with the Influenza Bacillus.—Dr. RUSSELL L. CECIL presented this communication, in which he stated that previous efforts to transmit influenza to man by inoculation with the influenza bacillus had been for the most part unsuccessful. These failures might have been due to one or more of several causes: (1) Natural or acquired immunity on the part of the subject. (2) Insufficient dose of culture. (3) Loss of virulence in culture used. In the experiments reported by the author, six healthy volunteers were inoculated in the nose and throat with a strain of *B. influenzæ* freshly isolated from a clinical case of influenza. Preliminary cultures showed that only one of the volunteers was a *B. influenzæ* carrier, and he denied having ever had the disease. Three out of the six volunteers gave a history of influenza during the epidemic of 1918; the other three denied having had influenza at any time, though they admitted frequent exposure. Two of the volunteers received washings from chocolate blood agar slant cultures of *B. influenzæ* (½ to 1 slant) in each nostril. Two others received the peritoneal exudate from a monkey with *B. influenzæ* peritonitis (0.1 c.c.) in each nostril. The last two received a six hour chocolate blood broth culture of *B. influenzæ* (0.5 c.c.) in each nostril. Five out of the six volunteers developed definite signs of infection, premonitory symptoms appearing four to six hours after inoculation. Headache and general malaise were soon followed by rhinitis, pharyngitis, and mild conjunctivitis, and in three instances by tracheitis. Backache was present in two cases; general muscular aching in two. Definite leucopenia was noted in three cases; in the other three the leucocytes were unaffected. Fever was absent in all five cases. Two of the patients were confined to bed for twenty-four to forty-eight hours. Symptoms lasted two to four days, except in one of the tracheitis cases where symptoms presisted for ten days. Strange to say the *B. influenzæ* carrier developed signs of infection, but ran a mild course. Smears from the nasal discharge and from sputum of infected cases showed pus cells and influenza bacilli, sometimes in large numbers. Cultures gave influenza bacilli, often in practically pure culture. In several cases influenza bacilli persisted in the secretions two weeks or more after inoculation. None of the volunteers developed pneumonia.

Dr. HANS ZINSSER said that it was difficult at the present time to discuss the etiology of influenza with anything like conclusiveness. Dr. Cecil's experiments on man as well as his work on monkeys unquestionably proved that the Pfeiffer bacillus could cause an upper respiratory catarrh, but whether this was truly influenza or not was still uncertain. It is impossible to correlate all the literature at the present time because of its size, since few physicians who had seen cases during the epidemic had failed to write some kind of report. During the early part of the influenza epidemic in France and other countries, many observers failed to find influenza bacilli, but this was unquestionably due to the fact that the technique was defective. We had now learned to manipulate this organism more perfectly, and with improved technique better results were obtained. In a large number of

examinations in various parts of the world the influenza bacillus has been found, if not as the predominating organism at least present in large numbers, the percentages ranging from 50 to 80 per cent of the cases examined. In a considerable number of cases it had been found in pure culture in the lungs, especially in children dead of bronchopneumonia. It has rarely been found in the blood stream. All experiments to produce influenza in human beings with pure Pfeiffer cultures had thus far failed. MacCoy and Rosenau had utterly failed to produce the disease in man with pure cultures, with nasopharyngeal mucus, and filtrates, using a large variety of methods. Their failures, if they did nothing else, showed us that negative experiments with pure cultures of influenza bacilli should not be taken to disprove their etiological significance, since MacCoy and Rosenau had used the combined material of the nasopharyngeal mucus of active cases, with negative results, and if one were to draw the most extreme logical conclusions from these experiments one would have to conclude that the disease was not conveyed by the respiratory secretions at all, a conclusion which of course is out of the question, and showed only the great difficulty attending such experiments and the great importance played by other conditions, such as the susceptibility factor, etc. Filtrable virus experiments had been done by a large number of men, and in some cases, as in the experiments of Yamanouchi, with apparently unqualified success. At least three observers in Germany claimed not only to have proven filtrable virus, but to have seen minute coccoid bodies either in culture or in sections of the lesions. Attempted serological proof of the relationship of the influenza bacillus had led to confusion. The experiments of Park and his coworkers had shown a remarkable variation in agglutination reactions of strains isolated from the same family during the epidemic. In Dr. Zinsser's own experiences during the early parts of the epidemic in France he and MacNeal found influenza bacilli in the throats of all of a small group of cases examined. The question could not be briefly discussed, therefore, because of the volume of confusing evidence. So far none of the filtrable virus experiments could be accepted as proven, and the association of the cases with the influenza bacillus was at least so strong that one could not exclude this bacillus until much more work has been done. Experiments such as those of Dr. Cecil were in the right direction, and he seemed to have produced a condition somewhat simulating influenza. However, Dr. Zinsser's idea was that the catarrhal inflammations such as those produced by Dr. Cecil, could very properly be regarded not as true influenza, but as one of the complications since true early cases often showed no catarrhal inflammation whatever. Dr. Zinsser asked whether the afebrile conditions produced with the cultures could be regarded as true influenza.

Dr. CECIL, in closing the discussion, said that as for demonstrating the cause of the pandemic, the only way to do that would be by producing another pandemic experimentally, and certainly no one wanted to do that. Dr. Zinsser asked if the experimental infection was similar to the disease as seen clinically, with fever, prostration, etc. In reply to this question he might say that there was some difference in the severity of the two diseases. Whereas it had been common to find extreme prostration in the pandemic, in the experimental infections the prostration was comparatively slight. Dr. Cecil said he would hesitate before pronouncing the experimental disease pandemic influenza.

The Electric Chorea of Dubini and Lethargic Encephalitis.—Sicard and Litvak cite the disease which occurred in Milan in 1846, described by Dubini as electric chorea. Other observers who reported cases were his pupils, Pignacca, Trua and Rommasi. The sleeping component was at first attributed to exhaustion due to the repeated cloni. The mortality was very high and of the thirty-eight known cases all but three ended fatally. Pupils of Dubini continued to keep track of the disease for nearly twenty years and in brief time the sleeping tendency was looked on as an essential phenomenon. There was no thought of transmission from man to man. As far as known the disease was not seen outside of Lombardy. Study of the cases causes the authors to uphold the view that the disease was encephalitis lethargica.—*Le Progrès Médical.*

Therapeutic Hints.

"Colds."—H. Laveson gives the following as the most effective general remedy in the treatment of "colds":

℞

Liquor potassii citratis
Liquor ammonii acetatis
Spiritus aetheris nitrosi āā.....3vi
Sodii benzoatis 3ii
Syrupi acidi citrici qs.....ʒiii
Misce.

Signa: A teaspoonful in water every two hours.
—*Indianapolis Medical Journal.*

Dissolved Sulphur in the Treatment of Psoriasis.—Louis Bory, who has been studying the remarkable action of injectable sulphur in psoriasis, has modified his original formula and now uses the following:

Pure precipitated sulphur	1 gr.
Guaiacol	5 gr.
Camphor	10 gr.
Eucalyptol	20 gr.
Sesame Oil q.s. to make	100 c.c.

He begins with injections of 6 c.c. as a minimum dose and 10 c.c. as a maximum, an average dose being 8 c.c. The febrile reaction is seldom well-marked, and is not more durable than with the infinitesimal doses originally employed. The initial treatment of the outbreak of psoriasis comprises four or five injections, at a week's interval. He usually waits until after the second injection and until the eruptive elements have begun to pale before inaugurating the local treatment. The most effective local treatment is to paint the elements with coal tar every other day. With this treatment two injections of sulphur will often suffice, and nearly all psoriasis patients are discharged from the hospital within three weeks.—*Medical Press and Circular.*

Constipation.—Roy Upham, in discussing the dietary treatment of constipation, gives the following formula for a special bread which he has found advantageous:

Two cups of wheat bran.
One cup of flour.
One teaspoonful of salt.
One and a half teaspoonfuls of baking powder.
Three tablespoonfuls of molasses.

Mix bran and flour, baking powder, salt, and molasses. Then add enough milk to make a dough. Various fruits, such as raisins, figs, and dates, may be added if desired. Bake the dough in the form of a loaf, or gems to vary the monotony. This same dough can also be steamed as a pudding and served with honey or other syrup.—*New York Medical Journal.*

Whooping Cough.—T. E. McMurray reports satisfactory results in the treatment of whooping cough by the use of benzyl benzoate. The dose given was from five to thirty minims every four hours. In some cases decided improvement was noticed from the smaller dose, in other cases larger doses were employed. In almost every instance the treatment determined subsidence of the paroxysms. The effect usually made itself felt within forty-eight hours, and as a rule the relief was immediate and complete.—*New York Medical Journal.*

Miscellany

The Visit of Laennec to Bordeaux in 1824.—According to the *Journal de Médecine de Bordeaux* for May 10, 1920, xci, 9, Professor Ollive of Nantes recently gave a very circumstantial account of a visit of the celebrated Breton physician to Bordeaux in the year 1824. The author is himself a Breton and has had special opportunities for historical research along these lines. Laennec himself was for a time a student at Nantes, where his paternal uncle resided, before finishing his education at Paris. The distinguished student was known as "little Laennec," for he was not only short in stature, but poorly nourished. He was already fighting the malady which was so soon to destroy him and had to make several trips home with this intent. During his short life he fought consumption as he fought those of the faculty who opposed his discovery. Two years before his death Laennec visited Bordeaux professionally. He proceeded directly from Quimper in Brittany to Langoiran near Bordeaux to examine a rich Spaniard by his newly discovered technique. The fee was 1000 pistoles, which then amounted to between 10,000 and 11,000 francs—about $2,000. He improved the opportunlity to visit the Saint-André Hospital at Bordeaux, where for two whole forenoons he demonstrated the use of his stethoscope to the Bordelais physicians. Some one, thought to have been a student, made a sketch of the visitor which still exists and shows in its reproduction in the *Journal* a short, thin man with a large head, wearing spectacles and clutching a stethoscope in both hands. It is thought that the caricaturist was aware of the fact that Laennec was skilled as a flute player and his attitude suggests that the stethoscope was a musical wind instrument. It is recorded of this hospital visit that Leannec was treated with studied politeness, but was unmercifully rallied or "joshed" about his new instrument. The better to illustrate the fallibility of human judgments it is added that in the notes of a consultation held about this time by the savant the entire modern treatment of tuberculosis was anticipated. The visit of Dr. Ollive had as an immediate outcome a movement to recognize the genius of Laennec in an appropriate way by Bordeaux physicians. It may be added that not a few members of the medical faculty are of Breton origin—Pousson, Denucé, Abadie, and several others.

The Perfume of the Human Body.—De Blasio writes briefly of this subject which, while a familiar one, seems to be continually enriched with data hitherto unpublished. There are racial and individual odors for consideration and the author excludes merely offensive excretions from certain regions of the body. The racial odor of the African is merely one of many racial smells. Explorers early placed on record the odor of the Caribs and Peruvians, Tartars and Arabs. The American aborigines were repelled by the odor of the Europeans, and the Peruvians even had words to indicate the odors of the latter and of the negro. The Japanese are distressed by the odor of the Europeans, and bad smelling individuals of their own race are refused for military service, while women with offensive axillæ have trouble in getting husbands. The number of distinguished men and women who exhaled aromatic odors is quite large, although in many articles on human odors but few examples are given. Not a few ecclesiastics, including saints, belong here and the subject borders on that of the "odor of sanctity," and may stand in some association with ascetic living. In none of the cases cited is the odor likened to any of the known perfumes. But it is otherwise with certain famous women favorites of monarchs, for Agnes Sorel gave off the odor of violets, Diane de Poitiers of amber, and Mme. de Maintenon of musk. The author has personal knowledge of a woman of middle age who exhaled the odor of violets. She was poor and an invalid and the scent was apparent when she entered the hospital for bronchitis. It was an inconvenience to her and had first been noted when she had a convulsive attack at the beginning of puberty and was more marked after emotional crises of a painful character. It could be traced to the left axilla. These aromatic odors are comparable to the bouquet of wines and doubtless proceed from the formation of certain aromatic ethers.—*La Riforma Medica*, 1920, xxxvi, 29.

Landmarks in the Treatment of Cancer of the Uterus.—We note in the May 15 number of *El Siglo Medico*, lxvii, 3466, two articles which bear from widely different angles on the same subject. One is the death notice of Wertheim of Vienna, which event occurred in February last, and the other is an account of the lecture delivered at Paris by Recasens, dean of the Madrid faculty, on the treatment of uterine cancer, he being one of the leading radium experts among gynecologists. The name of Wertheim is synonymous with the surgery of uterine cancer, and as his death took place at the early age of fifty-six surgery has sustained an incalculable loss. He began his medical career as a physician and his *chef d'œuvre* before he took up surgery was a monograph on the blood in leucemia. One year later he was operating under Chrobak in the gynecological clinic in Vienna. For seven years he was at Prague, where he worked especially at gonorrhea in the female and hysteropexy. Not until his return to Vienna in 1899 did he begin his work on cancer surgery and the radical operation which bears his name. In reference to Professor Recasens it is regarded by his Spanish colleagues as a great honor to Spain that he was invited to lecture at the Tarnier hospital on the treatment of cancer. His visit caused the greatest interest among the French gynecologists and was of international importance, even the diplomatic corps being represented. The subject, as already implied, was radium in uterine cancer, over which the speaker was enthusiastic. Other forms of radiation do not appear to have been touched on. Twenty-four per cent of cures were claimed by the speaker, who also asserted that the treatment of uterine cancer had been revolutionized. His remarks were received with the greatest enthusiasm and some of his auditors were affected to the point of tears. He received an ovation of singular warmth and many felicitations from his audience.

MAMMALOGY—AN ANATOMICAL AND TAXONOMIC CONSIDERATION OF THE GROUP TO WHICH MAN BELONGS.

BY R. W. SHUFELDT, M.D., C.M.Z.S., ETC.,
WASHINGTON, D. C.
MEMBER AMERICAN SOCIETY OF MAMMALOGISTS.

(*Concluded.*)

AN anatomical monograph upon any species of mammal, as a cougar or an opossum, makes a volume of very considerable proportions. To write out the complete morphological account of a shrew or field mouse takes quite as much space and labor as it does to furnish a similar history of the anatomical structure of a monkey or a man. It is evident, then, that in such an article as we now have in hand, only a very limited amount of space can be devoted to such a large subject as the anatomy of the Mammalia, and even the structure of our game mammals would furnish material for a series of volumes of no mean proportions. Still, the main anatomical points of mammals may here be pointed out, as well as the bearing that mammalian morphology has upon the classification of the class.

Mammals, instead of being more or less thickly clothed with feathers like birds, are furnished with a coat of hair, and no mammal is entirely without this hirsute modification of the epidermis or skin. Hairs have even been found upon the body of various species of whales, those huge and typically aquatic mammals of the great seas. Hair in mammals varies in a very marked degree, not only on the different parts of the body of the same individual, but in different species. These different kinds of hair may be seen in the soft and velvet-like coat of the common mole; in the tail of the horse; in the quills of the Canada porcupine; in the various kinds of ordinary fur; in the whiskers (*vibrissæ*) and eye-lashes (*ciliæ*) of all mammals; in the bristles of the peccary, and in the wool of the sheep. Often the stronger variety of hairs are, individually, controlled by a muscle in the skin, and the part of the coat thus endowed may be elevated or lowered more or less at will or when acting under the exhibition of certain of the emotions, as anger or fright. The bristling of the porcupine and the pig, for example, is thus explained. Again, other animals are furnished with scales (*Manitæ*), or with an exoskeleton (Armadillo); or scutes in certain regions, as under the tail in *Anomalurus*, or another form of them covering the tail of the beaver. Then others exhibit certain bare spaces or callosities, as on the inner side of the limbs of horses, on the sternum of the camel, and on the tuba ischii of apes. Many mammals develop horns and antlers of various kinds, but these have been touched upon more fully in another article.

It is among the cetaceans alone that we do not find the distal ends of the terminal joints of the digits of the limbs sheathed in epidermic coverings, or armed with dermal plates, constituting the nails (*unguis lamnaris* and *unguis tegalaris*), claws (*fulcula*), and hoofs (*ungula*) of mammals. And, among the *Monotremata*, there is a perforated spur attached to the posterior limb, on either side, in the males, having a special secreting gland in connection with it, the contrivance forming the weapon of offence.

Cutaneous and other glands also form a part of the anatomy of all mammals. Representing the former, we have the well-known sebaceous glands and the sweat glands, the former being universally distributed, while the latter, according to Dr. Claus, are absent only in a few cases, as in certain whales, mice, and moles (*Cetacæ, Mus, Talpa*). It is with hair follicles that the sebaceous glands are invariably associated, although they are often, too, found in the skin, where it does not support a hirsute growth or is entirely naked. They secrete a fatty substance for the purpose of keeping the skin pliable and soft. On the other hand, the sweat glands continuously secrete the sweat or perspiration, a function of great physiological importance. In certain parts of the body this may exhale a peculiar odor that, in some instances, excites the sexual instincts. It is, however, the larger glands of mammals that are thus, in numerous species, especially endowed. Other glands have no such function, while still others secrete fluids that, when discharged, are a mode of offence or defence, as in the case of the skunk. Sometimes these odorous substances secreted by the larger glands have for their object the recognition of the presence of the individual, usually of the opposite sex. Among the mammals to be treated in the present work, our deer and antelope possess such glands, and in addition thereto a suborbital gland of crumen. In the peccary we also find a lumbar gland, and a preputial gland in the beaver; a caudal gland among foxes, and interdigital glands among some of the ruminants. Many of these structures are well known and have been described at length; but they cannot detain us here, as my space forbids their discussion.

All mammals possess a perfectly developed bony *skeleton*, constituting a framework for the support and protection of the various tissues and organs of the body. The study of this part of their anatomy, from the earliest stages of fetal life up to and including the osteology of the adult, is one of extreme

interest, not to say importance. The study of the minute or histological structure of bone tissue itself is equally so. Then the wide and varied differences to be seen in the skeletons of the representatives of the several mammalian groups and families furnish material for other extensive studies, all of which can here be but barely suggested to the reader.

In all mammals, except in the armadillos and their extinct allies, the skeleton is completely internal, and for the convenience of description is divided into an *axial* and an *appendicular portion.* The first comprises the skeleton of the head and the trunk, and the latter that of the limbs. Few exceptions exist in this division, and they consist of the presence in some mammals of an *os cordis* and an *os penis.* Still more definitely we may say that the skeleton of the head comprises the skull and the bony parts of certain organs of sense, as for example those of the tongue (*os hyoides*) and the ear (*ossicula auditus*), while the teeth do not belong to the skeleton at all but to the tegumentary system, in common with the hair and other appendages of the skin. Passing to the axial skeleton, it is to be noted that, apart from the skull, it comprises the spinal or vertebral column which, posteriorly, is prolonged into the tail, the sternum, and, finally, the ribs.

During fetal life and in all sub-adult individuals among the mammalia, the various bones of the skull are independent; but when the animal has become fully adult, they, with more or less firm union, fuse together, leaving free only the lower jaw or mandible, the little bones of the middle ear, and the hyoid bone. This fusing together of the elements of the skull varies in different species and individuals, and becomes more complete with age and time. At all stages, however, we recognize in the skull the bones of the cranium and the bones of the face, the former being the osseous capsule protecting the brain, the latter the bony foundation upon which the features are moulded, and in and upon which not a few other parts and tissues find support and protection. Taken together, there are over twenty bones in the cranium and face; they have all received special names, and been described in a number of species, as the dog, man, cat, and the like, with the utmost detail and with various objects in view, as developmental, anatomical, or physiological, or to fulfill the requirements of comparison.

The *spinal* or *vertebral column* consists of a chain of separate bones called *vertebræ.* These vary in number and in their morphology in the various genera and families among the mammalia, but in all their general structure and characters are the same. In number they vary from about 26 to 40, and the length of the tail has not a little to do with it. Where the hinder limbs are fully developed, two or more vertebræ fuse together to form the so-called sacrum of the pelvis; while in armadillos and in certain whales some of the cervical or neck vertebræ fuse together. As in the case of the numerous bones of the skull, the various parts, processes, and characters of the mammalian vertebra have been described in works on anatomy and elsewhere with no end of detail. As a chain of bones we commonly divide it into several regions, as the cervical vertebræ or the bones of the neck; the dorsal vertebræ or those of the back—they being the ones to which the ribs are articulated; the lumbar vertebræ or those of the small of the back; the sacral vertebræ or those completing the pelvic girdle to assist in forming the bony framework for the support of the hind legs or pelvic limbs; and, finally, the caudal vertebræ or those found in the tail. When articulated together *in situ,* these bones are held in their normal relations by a series of ligaments, by the attachment of certain muscles, and by other tissues.

Through the entire chain, even to include a greater or less number of the anterior caudal vertebræ, passes a tubular viaduct for the transmission of the spinal cord, which finds its starting point in the base of the brain, and usually terminates somewhere in the tail. Along the entire tract of this *spinal canal,* each vertebra takes part in its formation. The interarticulation among the vertebræ is by the more solid anterior portion of these bones, technically called the body of the vertebra, and by certain vertebral processes. These projections or processes of the vertebral bones furnish the necessary surfaces, to which ligaments, the tendons of muscles, and muscles are attached. A material known as the *intervertebral substance* connects the bodies of the contiguous vertebræ. This material is elastic and more or less dense and tough, its purpose being not only to unite the vertebræ, but to insure their constant normal relations to each other after every act affecting the movements of the spine through muscular action. Opposite this intervertebral substance, we find, in the skeleton of the tail of some mammals, beneath the vertebræ, certain V-shaped bones called *chevron bones.*

In the middle line in front, placed longitudinally, is found another bone, or, in many instances, a series of bones, singly or collectively called the *sternum.* With it the *ribs* articulate upon either side, and thus connect it with the dorsal vertebræ of the spinal column. The form of the sternum varies greatly among the mammalia, though it is absent in none of them. Its anterior segment is called the presternum or *manubrium sterni;* all of its middle portion, whether composed of several pieces or one, is the "body" or mesosternum; while the posterior or distal end is called the xiphoid, xiphisternum, or the ensiform process. As with the other bones of the skeleton, the *ribs* vary greatly throughout the Class Mammalia; they vary in the matter of form, number, and their articulations. The "true ribs" join the vertebral column with the sternum; the "false ribs" pass from the vertebræ as the true ones but do not meet the sternum; they serially articulate with each other by their ventral ends. More posteriorly we may have a few ribs that are still shorter with free ends, these bones being designated as "floating ribs." Free ribs may also be attached to the distal one, two, or three of the cervical or neck vertebræ. The vertebral ribs of the dorsal region do not of themselves reach clear around to the sternum, for their circuits are completed by the "sternal ribs," and when these latter do not ossify, they are known as the "costal cartillages," which is their normal state in man and other mammals. The characters and morphology of the ribs have been described in great detail in works devoted to comparative osteology.

Turning next to a brief consideration of the *appendicular* part of the skeleton, we find it, as already stated, to consist in two pairs of limbs, an anterior and a posterior pair. The latter may be rudimentary in character, as in the whales, while the anterior pair is always present and fully developed. When enjoying complete development in both pairs, the limbs are joined to the axial skeleton by means of bony girdles. In the case of the anterior limb it is the *shoulder girdle,* and in the posterior or pelvic limb, the *pelvic girdle,* in many mammals existing only in a more or less rudimentary condition, or at least much modified as compared with other vertebrates. The monotremes form an exception to this. With respect to the pelvic girdle it is complete in all mammals save the cetaceans, in which group it is found to be exceedingly rudimentary. When fully complete, the shoulder girdle consists of three bones: the *scapula* or "shoulder blade," the *coracoid,* and the *clavicle* or the "collar bone." The first of these is always well developed, the collar bone may be absent in many, as for example in the bears; and it is only in the *Monotremata* (Duck-bill, etc.) that we meet with a complete coracoid. In most mammals this is reduced to a simple process. A consideration of the shoulder girdle throughout the mammalia is a very interesting study and a very important one—a statement that applies with equal truth to all parts of the appendicular skeleton. Here we can bestow upon it but the briefest notice possible.

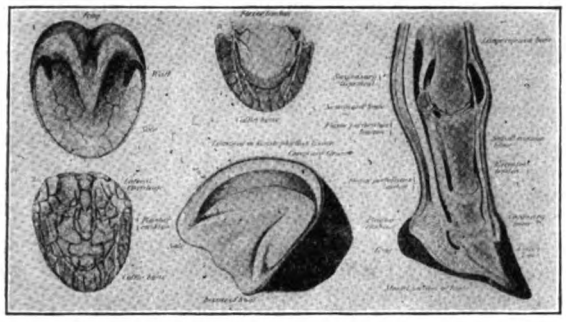

FIG. 9.—Anatomy of foot of horse. Photo by the author. Haines, del. ad. nat. et pinx.

The anterior or pectoral limb (arm in man and the apes; fore or front leg in the horse and many others), is made up of three segments. The upper segment, or the one that articulates with the shoulder girdle, has but the one bone: the *humerus* (brachium); in the next there are two: the *radius* and *ulna* (antibrachium; forearm); then follows the *carpus* composed of a number of small bones, and finally the bones of the hand or manus. This limb exhibits the greatest amount of diversity among the mammalia. To offer a hint as to the extent to which this may be carried, we may note that the ulna may become quite rudimentary in character and fused to the radius (bats); the number of digits, phalanges or fingers (never more than *five* in mammals) vary in the most remarkable manner. Extremes in this particular may be seen in the hand of a man and the hand of a horse, there being *five fingers* in the first instance and but one in the last. Similar and wide variations occur in the osteology of the carpus or "wrist joint." Normally it consists of two principal rows of bones, there being three in the proximal row and five in the distal with a central one. There are usually two additional ones called *sesamoids.* All of these small bones have been named, and even bear a number of names given to them by anatomists of different countries and at different times in the history of the science. Their number is often reduced in mammals, and they vary greatly in form throughout the Class.

The number of joints in the fingers of certain whales sometimes far exceeds what we meet with in the rest of the mammalia. This applies especially to the second and third fingers. In this group the hand is reduced to a paddle completely covered by a common integument. Bats have their fingers greatly elongated to support the flight-membrane. Indeed, the modifications presented on the part of the hand among mammals is well-nigh endless, it having in time become modified, in order to be adapted to the various uses to which it is put.

Much that has just been said above about the anterior limb applies with equal truth to the pelvic one.

The *pelvic girdle,* although fulfilling the same purpose with respect to the hinder pair of limbs that the shoulder girdle does with the anterior pair, differs from the latter entirely in form and in other particulars. Among the principal differences it must be noted that, when completely developed, it firmly articulates with the spinal column. In front the bones unite without the intervention of any bone corresponding to the sternum (pubic symphysis); and it differs in other points. This pelvis has two lateral halves each called an *os innominatum,* either half being composed of three bones, namely, an *ilium,* an *ischium,* and a *pubis* or pubic bone. They have their union in the hip-joint or socket termed the *acetabulum* for the articulation of the proximal bone of the limb, the *femur.* This latter corresponds to the bone of the arm (*humerus*) which, in some mammals, is the largest and heaviest long bone of the entire skeleton. It is the single segment that constitutes the thigh; while in the "leg," as in the forearm with which it corresponds, there are two bones, the *tibia* and the *fibula,* corresponding respectively to the radius and the ulna. Very often the fibula is more or less rudimentary in character and considerably reduced. In front of the articulation of the femur with the bones of the leg we find, in all mammals, the well-known sesamoid bone, popularly called the "knee-pan" or "knee-cap"; it is the *patella.* In passing we may note the two bones found in front of the pelvis

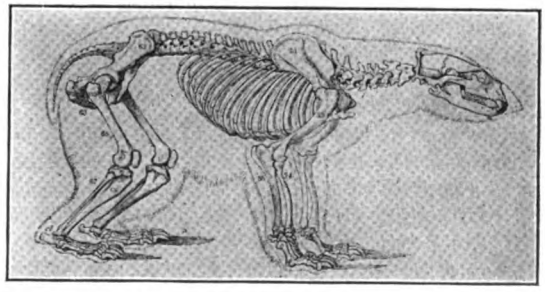

FIG. 10.—Skeleton of polar bear (*Ursus maritimus*). By the author after Owen. C, cervical vertebræ; 51, scapula; 53, humerus; 54, radius; 55, ulna; 62, pelvis; 63, pubis; 65, femur; 66, tibia; 67, fibula; *cl,* calcaneum or os calcis.

in marsupial mammals and in the monotremes. They articulate with the pubic and are known as the *epipubic* or *marsupial bones*. Our common Virginia opossum is the only animal possessing them in the United States fauna. Other small sesamoid bones are found about the knee-joint in certain mammals. They occur on its posterior aspect, and are technically known as the *fabellæ*.

There is much in the *foot* (pes) of a mammal to remind us of what was found in the distal segment of the fore-limb (hand, *manus*), it also being divisible into three parts: the *tarsus*, composed of more or fewer small bones like the carpus; the *metatarsus*, composed of a series of longish bones, as in the case of the metacarpus of the hand, and, finally, the phalanges of the digits or toes.

The arrangement and number of bones of the tarsus in mammals are not disposed to vary to the extent that they do in the carpus. Two are always found in the proximal row, and there may be as many as five others—four in the distal row, and the central one (*naviculare centrale*). Besides these, there may be certain sesamoids present, usually one on one side of the foot and one on the other, the one on the outer side being less often present. They occur principally among rodents and some of the carnivores, a third one being found among the Armadillos.

No mammal has more than *five metatarsal bones*, and, as in the case of the metacarpals of the hand, they may be greatly reduced in number. In the typical foot there are also *three* joints in each toe, except the big one (hallux), it having but *two*. This is likewise the numerical rule in the hand, where, too, the thumb (*pollex*) has but two phalanges.

The study of *the muscles* constitutes the science of myology of anatomy. Throughout the mammalia we find the muscular system to be very well developed; indeed, it is among mammals that it arrives at its greatest degree of perfection. In athletic men and women of the highest types, the muscles, perhaps, reach their limits of refined development. Very considerable variation exists in the myology of mammals, but their general plan and functions are the same throughout the class. They have been exhaustively studied in only a few species and genera, and they have by no means received, at the hands of morphologists, the comparative treatment that their importance warrants. There may be as many as 150 pairs of muscles in a mammal, and a number of unpaired or azygos ones. In the vertebrata, they constitute the flesh of any particular animal, while among cattle they are the lean of the meat, apart from the fat.

Muscles control the movement of the various parts and organs of the body, the majority of them being under the control of the will; while others, of a different histological character, are not so, as the muscles of the heart or of the intestines. These are called voluntary and involuntary muscles. Muscles vary in their action; in the fixed points of attachment to the skeleton or skin or other structures, and in their form, size and other characters.

As a rule, the *origin* of a muscle is its most fixed point, its proximal end, and nearest the central axis of the body; the other, or its distal extremity, is called its *insertion*. Frequently, they are *inserted* by means of *tendons*, and the bones to support the proper surfaces for these often develop spinal processes and tuberosities, as the "spine of the vertebræ" for the insertion of some of the muscles of the back.

The British anatomist, the late St. George Mivart, who paid very considerable attention to vertebrate myology during his life-time, said, in his *Lessons in Elementary Anatomy*, that "Muscles acting on bony levers produce definite *motions*, in consequence of which certain epithets are applied to such muscles.

"Thus, when two bones are united by a hinge-joint, muscles which by their contraction tend to make the angle formed by such bones acute are termed *flexors*. Those, on the contrary, which tend to open out such an angle are termed *extensors*. Some muscles attached to a long bone which is relatively fixed at one end, tend to make it describe the superficies of a cone, or a movement of *circumduction*. Such muscles are termed *rotators*. Some muscles move a bone away from a given axis, and are therefore termed *abductors*. Others tend to bring it towards such an axis, and such are called *adductors*. The epithets "*protractors*," "*retractors*," "*elevators*," and "*depressors*" (terms which require

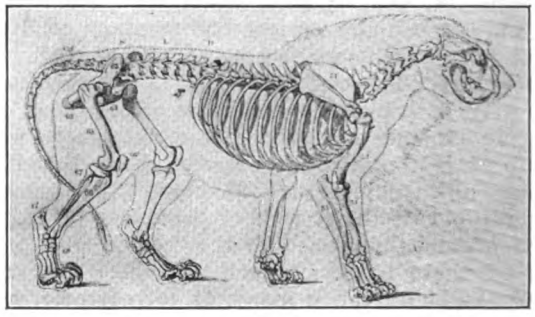

FIG. 11.—Skeleton of lion (*Felis leo*). After Owen. Lettering as in Fig. 14, with D, dorsal; L, lumbar; S, sacral, and C, caudal vertebræ; 51, scapula; 53, humurus; 54, radius; 55, ulna; 62, pelvis; 63, pubis; 65, femur; 66, tibia; 67, fibula; *cl*, calcaneum. Note the digitigrade foot in this mammal.

no explanation), are also sometimes made use of. There cannot, however, be any rational classification of muscles according to the functions they execute, because such functions often vary in different animals with regard to the very same muscle."

As to the classification of muscles, we may say that they are often considered as belonging to three groups namely, (1) the muscles of the exoskeleton; (2) the muscles of the endoskeleton; and (3) the muscles of the viscera. Examples of the first are seen in certain skin muscles, as those controlling the movements of the hairs and so forth. The endoskeleton system of muscles is large and includes the majority of voluntary muscles of the body. As in the case of the skeleton itself, they may be conveniently divided into those that pertain to the axial and the appendicular systems. In the last division occur the muscles of the viscera already referred to above.

Of course, it is quite out of the question to describe the muscles of any mammal here, as the subject is a very large one, and, moreover, my reader knows that I am not writing a work on anatomy. A number of years ago I produced such a book devoted to the muscles of a single species of bird—the Raven.

It printed several hundred pages, and took upwards of one hundred cuts of my own making to illustrate it. The description of the muscles of our antelope would demand the production of a volume of equal proportions—the deer family as a whole, several of them—particularly if the work was made comparative.

To study the muscles conveniently, however, the student should first consider those of the *head and neck;* these include the interesting groups controlling the movement of the eyes, the ears, the tongue, the expressions of the face, and a good many others.

The *muscles of the back* and the *abdominal region* number many pairs, and are responsible for producing a vast variety of movements. There are 32 pairs of muscles in the back of man, and not a few other animals are equally as well provided. Then we have to consider the splendid series of *muscles of the limbs*—the upper and lower extremities. Finally, I may speak of that very important muscle of respiration, called the *diaphragm* or "midriff," which Mivart speaks of as that "partly fibrous, partly muscular partition between the thorax and abdomen, perforated for the passage of certain organs," as the œsophagus and great blood vessels. In studying the muscles in the mammalia, one can very profitably read what Professor Mivart has said about them in his "Lessons in Elementary Anatomy;" Mr. Huxley in his "Anatomy of Vertebrated Animals;" Prof. Sir Richard Owen in his "Comparative Anatomy and Physiology of Vertebrates;" in the works of Chauveau, of Gegenbaur, and of a very long list of other comparative anatomists.

With respect to *the Digestive System,* it is to be briefly noted that it presents the widest imaginable variation among mammals. Only its main, salient points can be referred to here. Taken as a whole, the digestive tract consists of a tubular passage presenting certain cavities and dilatations for examination and associated with certain accessory organs. This passage has an anterior orifice, the mouth, and a posterior one, anus. In large part it is muscular in structure, thus insuring the transmission of the food through it, while other structures aid in preparing it for absorption by the body, as the teeth for its mechanical division, and various secretions from glands for its chemical preparation. In these operations the *mouth* and its different structures are important adjuncts. Muscular *lips* guard the entrance of the former, and these, to a greater or less extent, are prehensile in their function, as is also very frequently the *tongue,* the latter varying remarkably in character, being long and extensile in some mammals and rudimentary in others (porpoise). This is the principal organ or taste, and its superior surface is supplied with special papillæ and nerves for that purpose. It is supported by the *hyoidean apparatus.* From the view-point of the classifier, the *teeth* in mammals are exceedingly important structures. These arm the two *jaws* when present, but they may be entirely absent as in *Manis, Echidna* and *Myrmecophaga.* Their vast variety is well known and will not be dwelt upon in this place.

So far as known, never more than *four* pairs of salivary glands open into the mouth or buccal cavity. These are the *parotid,* the *submaxillary,* the *sublingual,* and the *zygomatic gland* (rare). They secrete the saliva, a fluid possessing important digestive functions, as well as those of softening the food in order that it may be swallowed with ease. They open by special ducts having special names. After it has been acted upon by the mouth-parts—an extensive action in many mammals but practically amounting to almost nothing in others—the food passes to the *stomach* through a muscular tube called *œsophagus.* In the majority of mammals, the former is merely a muscular pouch or sac, while in exceptional species and genera it becomes a wonderfully complicated structure presenting several divisions. The stomach may have several coats (muscular, serous, etc.); always a *cardiac* or esophageal opening, and a *pyloric* or intestinal one. Its inner coat is glandular (peptic glands, etc.) that have for their function the secretion of the *gastric juice,* an important adjunct in digestion. The manifold variations seen in the stomach of mammals is extended to their *intestinal tracts.* This digestive, muscular and glandular tube extends from the stomach to the anal orifice. Sometimes it is found to be simple, cylindrical, and of fairly uniform caliber. It may be divisible into a large and small intestine, strongly marked as in man. The former is again divided into *colon* and *rectum,* and the latter into *duodenum, jejunum,* and *ileum.* These last divisions are quite artificial. Often a blind pouch or *cæcum* is found at the junction of the large and small intestine. It varies in its development to a remarkable degree, and its study is one of great importance in mammalian anatomy. Glands of divers kinds beset the inner coat or lining of the intestines, and these secrete fluids that aid in digestion, or else are absorbent glands belonging to the lymphatic system. These *villi* occur only in the small intestine—a part of the tract that is curiously sacculated (*valvulæ conniventes*) and otherwise modified to carry out its particular functions.

Outside the main intestinal canal, we meet with two other glands of very considerable size which belong to the digestive system. These are the *liver* and the *pancreas.* The former, an organ of considerable importance, is found throughout the mammalian group. Its secreting duct is the *bile duct,* coming from the *gall-bladder,* and passing to the duodenal division of the small intestine. In some mammals, however, the gall-bladder may be absent; when present, the *bile duct* and the *hepatic duct* unite to form a common duct (*d.choledochus*) that has a similar destination. The liver is usually divided into *lobes,* but it may be more or less simple. For instance, in the rodent *Capromys,* the liver consists of many very small lobules, while in the Dolphin, there are but *two lobes* developed and very small.

We stand in need of far more extensive studies of the liver as found among mammals, which studies should be made comparative, and with the view of arriving at uniform nomenclature and descriptions on the subject.

The *pancreas* ("sweetbread")—another important secretory gland, furnishing the "pancreatic juice," another important digestive fluid passed into the small intestine through the pancreatic duct—is usually situated in the neighborhood of the stomach in mammals, and subject to great variation in different genera and families. It is more complex in a

bear than it is in man, and, as in the case of some of the *Canidæ*, may have two ducts. It is trilobed in the pig, and, according to Mivart, presents a beautiful, arborescent structure in the hedgehog and flying fox. Its duct enters the small intestine in various ways.

We find a serous membrane lining almost the entire abdominal cavity and reflected upon its contained organs and structures. This very complex structure is called the *peritoneum*. It is a completely closed sac, having its own proper cavity, and simply embraces the structures it encloses. Although present in all, it varies greatly in different mammals.

"The blood of mammals," says the late Sir William Henry Flower, "is always red, and, during the life of the animal, hot, having a nearly uniform temperature, varying within a few degrees of each side of 100° Fahr. The corpuscles are, as usual in vertebrates, of two kinds—(1) colorless, spheroidal, nucleated, and exhibiting amœboid movements; while (2) the more numerous, on which depends the characteristic hue of the fluid in which they are suspended, are colored, non-nucleated, flattened, slightly biconcave disks, with circular outline in all known species except the Camels and Llamas, where they have the elliptical form characteristic of the red corpuscles of nearly all the other vertebrates, though adhering to the mammalian type in absence of nucleus and relatively small size. As a rule they are smaller as well as more numerous than in other classes, but vary considerably in size in different species, and not always in relation to the magnitude of the animal, a Mouse, for instance, having as large corpuscles as a Horse. Within the limits of any natural group there is, however, very often some such relation, the largest corpuscles being found among the largest species and the smallest corpuscles among the small species of the group, but even to this generalization there are many exceptions."

A study of the blood naturally leads us to the anatomical consideration of the *heart*. The organ is, in the mammalia, always divided into *four* distinct chambers or cavities. It varies in form, however, throughout the Class, while in most of the ungulata a bone is developed in its central tendinous portion. The four cavities of the heart are the two auricles and the two ventricles, an auricle and a ventricle being upon either side or half. For the entrance and exit of the blood a number of openings occur, and several of these are guarded by a variety of valves, all of which is set forth in detail in works on anatomy. Mammals alone among vertebrates have the right auriculo-ventricular valve tendinous, as in the case of the left, it being flap-like in structure and held in position by fibrous cords. It is only in the Australian Duck-bill and its allies that we meet with the transitional conditions between this and what obtains in birds and reptiles.

Throughout the mammalia we meet with as much variation in the anatomy of the *blood vessels* as we do in the morphology of the heart or the central organ of the circulation. These differences in the blood vessels can be employed with advantage in the classification of mammals, as they hold true for certain natural groups. All mammals possess an aorta through which the supply of red blood is forced by the action of the heart to all parts of the body. The mode of branching of the aorta differs in different mammals, for example, in nearly all cases there is an innominate artery as a primary aortic branch, composed of a union of the carotid and right brachial. These vessels may, in other orders, be given off independently from the aorta—in this event, however, the aorta subsequently passes through the diaphragm to become the abdominal aorta, and to supply the lower part of the body with blood, through its many branches. Various large *veins* again return the blood to the heart, as the *vena cava superior*, and *inferior*, and those of the *portal circulation*. Only arterial blood goes to the kidneys and is returned to be emptied into the inferior vena cava. Both the anatomy and physiology of the venous system in many mammals is extremely interesting, and presents many differences, some of which are, as yet, but little understood.

All mammals have a highly developed *lymphatic* or *absorbent* system, the soft tissues of the body being supplied with *lymph* through its many ramifications. This lymph is a colorless fluid containing nucleated corpuscles, to which is added the *chyle* during the process of digestion. The chyle is taken up by the lacteal system of lymphatics from the small intestine, to be finally discharged into the general vascular system, to mingle with the venous blood. The lymphatics of the body unite to form two main trunks, the larger being the *thoracic duct* coming from the posterior moiety of the animal. There is also a system of *lymphatic* glands through which the lymph is conducted, and the ducts of this system, as in the case of the veins, are supplied with valves.

Other glands, known as the *ductless* glands, are found in the mammalia. They are associated with the lymphatic and vascular systems, and their entire physiology has not, as yet, been satisfactorily explained. The *spleen*, the *suprarenal capsules*, the *thyroid gland*, and the *thymus* are the most important examples of these.

Passing to the *Respiratory system*, we find that throughout the mammalia it has attained to a very high degree of development, and the organs and structures composing it not only vary considerably in many of the representatives of the group, but possess special interest for the anatomist and naturalist. Some mammals breathe through their mouths, and its anatomy has been briefly described above, while in addition thereto most species respire through the *nostrils*. These, with the exception of some cetaceans, are invariably paired. They open in various localities as at the extremity of the trunk in the Elephant, or far back on the head in the Whale. From these external apertures of respiration the air is conveyed to the lungs by means of the tube known as the *windpipe* or *trachea*, the distal end of which is modified in various ways to form the organ of voice, called the *larynx*. Another important organ, or rather structure, connected with respiration is the midriff or *diaphragm;* but this has already been touched upon when describing the muscular system. Above it we find the *lungs* suspended in the thoracic cavity or chest, one being upon either side of the heart, which is placed more or less centrally and enclosed by them. This free suspension of the lungs in the cavity of the chest is by means of the bifurcated root of the windpipe, and the pulmonary veins and arteries—vessels that

pass the blood from and to the heart respectively from the lung tissues. The latter is intimately covered all over by the thin, serous membrane called the *pleura*. In various mammals the lungs exhibit a greater or less degree of lobulation, there being five such *lobes* in man—three for the right lung and two for the left. Mivart says the common European porcupine has six in the right and five in the left. They offer many variations throughout the class.

Finally, there is to be considered the *air-sacs*, remarkable vacuities into which the external air may or may not be admitted. Their use is not always clear. They are found in several localities in the skull of man, and still more highly developed in the Elephant. Sometimes they are associated with the larynx, best seen in some of the Apes.

With respect to the *Urinary System* it is necessary to mention the presence of a pair of *kidneys*, from which pass the *ureters*, one from either organ, to open into the *bladder*. In the latter the urine

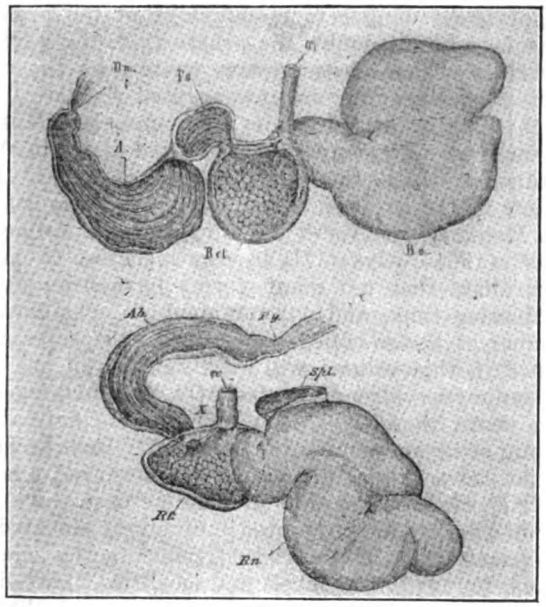

FIG. 12.—Stomach of a sheep (upper) and of a Musk deer, *Fragulus* (lower); *œ*, œsophagus; *Rn*, rumen; *Ret*, reticulum; *Ps*, psalterium; *A*, *Ab*, abomasum; *Du*, duodenum; *Py*, pylorus.

collects, to be discharged from time to time through the *urethra*. In the monotremata the ureters open into the urogenital canal, instead of into a bladder, thus simulating the structure in the Sauropsida. As a rule, in the mammalia, the *Nervous System* and *Organs of Sense* have arrived at their highest stage of perfectness and specialization. In the first-mentioned it consists of a more or less complicated *brain* with its associated parts; the twelve (12) pairs of nerves that commonly issue from it; the *spinal cord*, and the structures making up the *sympathetic nervous system;* while in the second we have to consider the anatomy of the organs of sense, as those of taste, of touch, and the senses of smell, sight, and hearing.

Finally, as to the *Reproductive System*, a very extensive field is opened for the studies of the researcher in mammalian anatomy; for not only are we called upon to consider the morphology of the structures composing and entering into it, but the organs of generation are different in the two sexes, and again very different in various orders of mammals. Then, in a way, we are here, too, to investigate the matter of secondary sexual characters, and the entire subject of the development of the young throughout fetal life to include, at last, the stage where complete development has been reached. Brief references will be made in other articles to be elsewhere published, to some of the peculiarities of the reproductive system in our game mammals, as well as to not a few of the secondary sexual characters that distinguish the sexes, especially as to peculiarities in coloration; the presence of manes or other hairy appendages, as the Bison's beard and the Moose's "bell"; the antlers of the Deer; and the horns of the *Bovidæ*.

In the classification or the taxonomy of mammals we adopt precisely the same methods that are employed in all classification, or the natural and orderly arrangement of any other group of animals, as for example, birds, fish, or reptiles. My views upon the classification of the Class *Aves* have already been presented in *The American Naturalist* several years ago,* and at the close of the present article I shall offer a similar provisional scheme of classification for the Class *Mammalia*. What I have said in regard to the principles of classification in the case of birds in my *Naturalist* paper is equally true with respect to existing and extinct mammals; for, as in the Class *Aves*, all of the various groups, from the lowest to the highest, bear a true relation to each other, for times both past and present. Such relationships exist among all forms that ever have or ever will appear upon this planet. It is the aim of science to discover exactly what these relationships in nature are, and by some means, as graphic as possible, make record of them.

True relationships, in the case of any group or groups, can only be discovered through the application of the sum of our knowledge of the forms to be classified to the solution of the problem. Our knowledge of the kind referred to falls into several distinct departments, as for example, palæontology, geographical distribution, morphology, physiology, habits, and other considerations. As to the pictorial and printed methods of exhibiting and expressing our views upon the classification of the Mammalia, what I have said in the case of Birds, in the above cited paper, is equally applicable to the Class here to be considered, and that account renders repetition in this place unnecessary. As will be seen beyond, the *lineal scheme* has been adopted as in the case of *Aves;* though, with the view of making the classification clearer and more useful generally, I have given the vernacular name of a typical example of each family in parenthesis immediately following its scientific name in the scheme. As but comparatively few fossil birds have been discovered and described, and the relationships of the existing forms being more or less evident or often shedding light upon the subject, these distinct avian species were incorporated into the classification I made of the existing families and higher groups of the Class.

*Shufeldt, R. W.: "An Arrangement of the Families and the Higher Groups of Birds," *Amer. Nat.*, vol. 38, Nos. 455-456, Boston, Mass., November-December, 1904, pp. 833-857, Figs. 1-6.

Now in the scheme of classification here presented of the Mammalia, this feature has been omitted, owing to the several facts that a very much larger number of fossil mammals have been described than birds; that they elucidate more the origin and lines of descent of certain existing mammalian families rather than they do the relationships of the latter; finally, in not a few instances, their relations to existing mammals is not entirely clear, and where it is clear, the fossil forms would merely tend to swell the list of the existing ones without adding anything to the value or completeness of the taxonomy proposed. So for all these good and sufficient reasons I am of the opinion that, at present at least, we are hardly prepared to include in a classification of existing mammals those which we only know by their fossil remains—certainly not in all instances. For example, we are by no means sure that the animals, by many thought to be Triassic mammals, may not, after all, turn out to be anomodonts, and this is probably true, too, of some of those of the Jurassic, which are known to us only through very fragmentary remains. Therefore, to include in my classification such extinct groups as the Polyprotodontia and the Multituberculata, placing the former near the marsupials and the latter near or with the existing monotremes, would neither avail nor mean much; moreover, the relationships are by no means proven.

The horse, deer, camel, rhinoceros, hippopotamus, pig, and various other lines represented by a great quantity of fossil material, would fit in much better, and, in the case of those of the most recent geological horizons, would, in numerous instances, simply fall into modern existing families, and so not affect classification at all. As we trace the ancestors of many of these, however, through the more or less abundant material at hand, we find ourselves soon confronted with vastly different forms, the relationships of which to existing mammals are by no means understood and settled, and it would be more than provisional to include them in any scheme of classification of existing Mammalia. This is all that is necessary to say upon this point. The mammalian taxonomers of some century of the future may be prepared, perhaps, to combine in a classification the then extinct and existing mammals, or even to draw a fairly correct "Phylogenetic Tree" for the Class; but we have not the requisite knowledge, much less the material, at this time.

There have been a great many classifications of the Mammalia proposed, the earliest ones dating far back into remotest history. Crude and unnatural, the first attempts in this direction are now considered by systematists as mere antiquities and curiosities of biological literature, and it is only within comparatively recent times that mamalogists are arriving at anything like unanimity of opinion in the matter, which is the best evidence we have that we are gradually approaching the long-desired goal of the true natural scheme of arrangement for the Class. It is now at least safe to say that we are upon the right road, and any conscientious work done along that road ought to prove to be of use and value, as well as a real contribution to the subject.

It would be quite impossible, if not altogether out of place, to discuss in an article like the present one the merits of any of these earlier attempts to classify the Mammalia, such as the ones proposed by Linnæus, Ray, Cuvier, Owen, Huxley, Flower, Milne-Edwards, Gill, and others; nor will it be expedient to enter into a discussion of the systems proposed by modern writers on mammalian taxonomy, as that, too, would require the limits of a small volume to properly treat of such a theme. I have carefully studied and taken into consideration all such contributions while engaged upon the arrangement here proposed, and for this the student must accept my word. Personally, I have studied all the habits, history, and structure of mammals continuously for the better part of half a century, and it was not until I had passed through such a schooling, both in the museums and in the field, that I felt at all competent to touch upon the subject of their probable relations to each other and ventured to offer a scheme for their arrangement; I trust the present work will bear me out in this statement.

The great danger to mammalogy at the present time is, without doubt, the practice, on the part of a certain school of descriptive writers on the subject, of encouraging an unwarranted specialization in the making of subspecies of mammals. This is deplored by a no less conservative and distinguished naturalist than the late Daniel G. Elliot. Dr. Elliot, in the preface to his work, "A Synopsis of the Mammals of North America and the Adjacent Seas" (1901), says: "It is very manifest to many naturalists that too many forms have been given distinctive rank, and without doubt a considerable number of the so-called species and subspecies contained in this volume will eventually swell the list of synonyms already sufficiently formidable. In late years there has been an evident inclination among some mammalogists to magnify unduly, as it would seem, trivial dissimilarities observed among their specimens, and thus greatly increase the number of slightly differentiated individuals elevated to a separate rank, at the risk of reducing the science to one founded upon labels and localities, instead of distinctive and prominent characters, and thus a knowledge of the place where an example was obtained becomes at times of more importance for its identification than are the differences that may separate it from its allies. The lack of resemblances often observed among crania is frequently but the individual variations of a type, and taking these for the characters upon which to establish a new species is apt to lead into error, and not in a few instances too much reliance has been placed upon such slight differences. The same may be said of shades of color, and not a few names in this Synopsis have been given to specimens so closely alike that one author, in speaking of his Key which was intended to be the means for distinguishing the species, has been obliged to say: 'It will be necessary to have both skins and skulls in hand, and even then *it will be impossible to identify some of the forms without actual comparison with their nearest allies.*' (Bailey: Revision of N. Amer. Faun. No. 17, p. 14.) The scientific value of such species (?) can only be very questionable at the best, and the elevation to a separate distinctive rank of such intimately related creatures can not

be considered as helpful or beneficial to mammalogical science. It can be safely asserted that there is hardly a genus of North American mammals that does not contain too many forms, and that the science would be benefited if a considerable number were relegated to their proper place among the synonyms."

The complaint Dr. Elliot makes here is, without doubt, well founded, but it is a difficult matter to apply his remedy. It is extremely difficult to know where to draw the line, although it is very evident, on the other hand, that in the case of a certain school of mammalogists in this country the refinements of species and subspecies making, has, with some mammals, been carried altogether too far. Indeed, we are almost led to doubt, and with justice, that they appreciate the operation of the law of organic evolution; the matter of color variation in very closely allied forms of mammals, and the value to be placed upon the skeletal and dental variations within the species. To apply the laws of natural classification to mice and ground squirrels presents precisely the same difficulties as the ones encountered when we come to apply those same laws to classify the representatives of the genus *Homo*. We find no trouble in drawing specific lines in the case of an Esquimaux and a Congo negro; but where are we to draw the correct subspecific lines among the commingled white races spread over the continent of Europe and elsewhere? But this is altogether too extensive a subject to discuss in this place, as it would be impossible to give it the full attention that its high importance demands. Moreover, I can afford to shirk any such responsibility here, as my classification of the mammalia, given beyond, carries the arrangement down only to include the families; fortunately these families are not built up upon an enormous collection of subspecific forms, having existence only in the minds of those who must create them in order to live and be recognized.

As in the case of *Aves*, the mammalia are completely isolated from all other groups of existing animals, and, moreover, this is found to be true when we come to take the extinct forms into consideration, in so far as they are at present known to us; this very much simplifies the matter of their classification.

In considering the primary divisions of existing mammalia, it is to be observed that they fall naturally into three clearly defined groups, or subclasses, which by De Blainville were designated as the *Ornithodelphia*, the *Didelphia*, and the *Monodelphia*. Many zoölogists still employ these terms, but the less objectionable ones proposed by Huxley in 1880 are coming into more general use. He substituted for these terms the *Prototheria*, the *Metatheria*, and the *Eutheria*, respectively, and I employ them in my own classification.

There are but two families of existing mammals contained in the *Prototheria*, namely the *Ornithorhynchidæ* (the Australian duck-bills), and the *Echidnidæ* (the spiny anteaters); they are the lowest forms of existing mammals known, having a very primitive anatomical structure.

All the existing marsupial animals of the world have been grouped in the *Metatheria*. Australia is the great region for these, while in the United States there is but one representative, the opossum. Structurally, the *Metatheria* stand between the *Prototheria* and the *Eutheria*. Their young are born in a very much undeveloped condition, and are transferred by the mother to the *marsupium*, where they are attached to her nipples, and subsequently grow, being nourished by the milk injected into their mouths by a special muscle of the mammary glands.

By far the great bulk of existing mammals belong to the *Eutheria*, or placental mammals. Throughout this great group the young, or fetus, is invariably nourished during its development within the womb of the mother by its attachment through an umbilical cord with an allantoic placenta. Exceptions to this rule are merely to be regarded in the light of accidents, as in the case of extra-

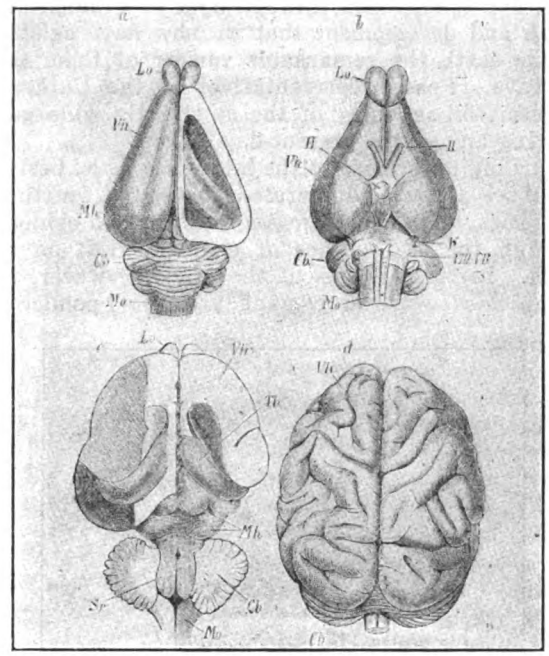

FIG. 13.—Brains of Mammalia. By the author after Claus. *a*, Brain of rabbit from above; the roof of the right hemisphere is removed so as to expose the lateral ventricle. *b*, The same from below. *c*, Brain of cat; on the right side the lateral and posterior part of the hemisphere is removed, and almost as much on the left side, and the greater part of the hemispheres of the cerebellum have been removed. *d*, Brain of orang (*a*, *b*, *c*, after Gegenbaur; *d*, from the Règne Animal.) *Vh*, cerebral hemispheres; *Mh*, corpus quadrigeminum; *Cb*, cerebellum; *Mo*, medulla oblongata; *Lo*, olfactory lobe; II, optic nerve; V N, trigeminal; VII, VIII, facial and auditory nerves; H, hypophysis cerebri; *Th*, optic thalmus; *Sr*, sinus rhomboidalis.

uterine pregnancies, and other departures from the normal course.

While the *Prototheria* and *Metatheria* have practically come to a standstill as a group of mammals, in so far as further development is concerned, the *Eutheria*, on the other hand, is still evolving with a powerful impulse toward specialization in morphology, mentality, and general organization. It includes mammals of the widest possible variation in form, as men and mice, bats and whales, elephants and shrews—and yet they are all more or less linked together by anatomical and other bonds, the interpretation of which there can now be no shadow of doubt.

Among existing *Eutheria* there are at least three groups that can at once be differentiated from all

the others; these are the *Edentata*, containing the armadillos, sloths, and anteaters; next the *Sirenia*, containing such large aquatic herbiverous mammals as the dugongs, the manatees, and some fossil forms closely allied to them, as the *Rhytina*, and others; finally, the *Cetacea*, a group containing the various species of whales, porpoises, and dolphins.

With respect to the remaining groups it is clear that they are more nearly related to each other, notwithstanding the great diversity of form to be seen among them. Although endowed with wonderful differences in the matter of their dentition, the dental formula is, nevertheless, the same throughout; that is to say, all in the permanent dentition, whatever their modification, may be derived from the general formula of 44 in the two jaws. Paleontology has gone far to show that the *Eutheria* have all sprung from a common, general type, and it has been through ages of gradual evolution and development that we now have existing on the earth the remarkable variety of them that we have. Fossil representatives of the *Eutheria*, however, fill in many of the apparently wide gaps existing among the present-day orders.

Turning once more to the latter, we have, besides the three already enumerated above, the fourth in the series, or the *Proboscidea*, now only in evidence through the two species of elephants left on the earth. In former ages of the world, however, the *Proboscidea* was an elegant array of ponderous

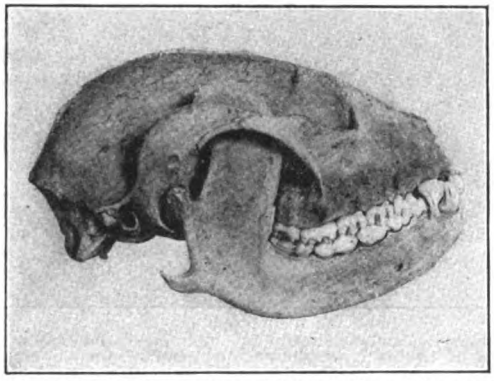

FIG. 14.—Right lateral view of the skull and lower jaw of the Cat-bear or Panda (*Ælurus fulgens*). By the author, natural size, from a specimen in the Academy of Natural Sciences of Philadelphia. Note the remarkable dentition of this curious Himalayan carnivore; it is allied to the raccoons.

animals, rich in species, and vast in numbers. They included the mastodons, the mammoths, and the *Dinotheria*, with their allies. And, as hinted above, we may add, that undoubtedly, through the extinct *Dinocerata*, the elephant forms are, in a way, though nevertheless really, linked with modern, ungulate animals, such as horses, pigs, tapirs, all the ruminants, and the rhinoceroses.

Another somewhat isolated group is represented by a very few and small Old World species known as Conies (*Hyrax*). Some mammalogists consider them to form an order (*Hyracoidea*), while others relegate them to subordinal rank.

As I have elsewhere said, the discovery of fossil mammals, both nearly and remotely related to the ungulate series (*Ungulata*), is constantly tending toward a rearrangement of these forms, and it may be that in the future this order will be much extended—even possibly to include the *Proboscidea* and the *Hyracoidea*.

Another great group is seen in the *Rodentia*, and one that is more or less clearly differentiated from all the other orders. As we know, it includes all the existing species of gnawing mammals, or the rodents, abundantly represented in the various families of rats, squirrels, marmots, and their various allies. So far as existing species is concerned, their common dental formula isolates them completely, while some discovered fossil forms point to their probable kinship with the ungulate series. (Compare the *Mesotherium* and the *Toxodontia*.)

Two other now extinct orders are recognized in the *Insectivora* and the *Carnivora*, but we find them to be far more closely allied when we come to study the discovered fossil remains of mammals as above pointed out. Especially does this apply to those early and primitive carnivores, called by Cope the *Creodonta*. Professor Flower seemed to believe that the "transition from the insectivores to the lemurs is not great, and, strange to say, however different they now appear, the early forms of lemurs are not easily distinguished from the primitive ungulates."

Allied to the *Insectivora*, we have another very distinct order of existing mammals. This includes, and only includes, the order *Chiroptera*. They, as we well know, are all volant mammals, possessing extraordinary modifications of their pectoral limbs, in the way of alar membranes stretched between the immensely elongated fingers.

In the last order of all, namely the *Primates*, we place the various subspecies of men, and all the various family groups containing the apes, monkeys, and their allies.

Through what forms, either extinct or existing, the *Hominidæ*, the *Pongiidæ*, and other simian families, are linked with the mammalian orders nearest allied to them, is a question not yet definitely settled. The secret is still locked up in the crust and caverns of the earth, though the researches of the palæontologist and the archæologist are slowly but surely solving this great, and to man, very important problem.

Within comparatively recent years a number of fossil or subfossil forms of very primitive types of men, including the extinct Pithecanthropi, have been discovered in different parts of the world. These point with ever-increasing clearness to the relation of this family to the stock from which both *Homo* and the simians are derived in prehistoric time. Such material is of the utmost importance and significance; but it is quite out of the question to enter upon its description here, more particularly as every intelligent person now fully recognizes the fact that man sees his nearest relatives in the existing simians; that he belongs in any complete scheme of classification of the mammalia that we undertake to make; and that he is, and will ever be, just as much subject to the law of evolution as any other mammal, living or extinct.

My present views, then, on the classification of the mammalia are set forth in the following arrangement:

A CLASSIFICATION OF THE MAMMALIA.

Kingdom: Animalia (animals).
Phylum: Vertebrata (vertebrates).
Branch: Craniata (skulled animals).
Class: Mammalia (mammals).

CLASS MAMMALIA

SUBCLASS I. PROTOTHERIA. (Lowest Mammals.)

Order I. MONOTREMATA. (Monotremes.)

Suborder	I.	MONOTREMATAFORMES	(Monotreme Animals.)
Family	I.	Ornithorhynchidæ.	(Duckbill.)
	II.	Echidnidæ.	(Echidna.)

SUBCLASS II. METATHERIA. (Marsupials.)

Order II. MARSUPIALIA. (Existing Marsupials.)

Suborder	II.	MARSUPIALAFORMES.	(Marsupial Animals.)
Superfamily	I.	Polyprotodontoidea.	(Carnivorous Marsupials.)
Family	III.	Didelphidæ.	(Opossums.)
	IV.	Dasyuridæ.	(Dasyure.)
	V.	Peramelidæ.	(Bandicoot.)
	VI.	Notoryctidæ.	(Pouched Moles.)
Superfamily	II.	Diprotodontoidea.	(Diprotodont Marsupials.)
Family	VII.	Macropodidæ.	(Kangaroo.)
	VIII.	Phalangistidæ.	(Koala.)
	IX.	Phascolomyidæ.	(Wombat.)

SUBCLASS III. EUTHERIA. (Placental Mammals.)

Order III. EDENTATA. (So-called Edentate Mammals.)

Suborder	III.	LORICATA.	(Armadillos.)
Family	X.	Dasypodidæ.	(Armadillo.)
Suborder	IV.	TARDIGRADA.	(Sloths.)
Family	XI.	Bradypodidæ.	(Sloth.)
Suborder	V.	VERMILINGUIA.	(American Ant-eaters.)
Family	XII.	Myrmecophagidæ.	(Ant-eater.)
Suborder	VI.	PHOLIDOTA.	(Scaly Ant-eaters.)
Family	XIII.	Manidæ.	(Manis.)
Suborder	VII.	TUBULIDENTATA.	(Aardvarks.)
Family	XIV.	Orycteropodidæ.	(Aardvark.)

Order IV. SIRENIA. (Sirenians.)

Suborder	VIII.	RHYTINAFORMES.	(Herbivorous Cetaceans.)
Family	XV.	Manatidæ.	(Manatee.)
	XVI.	Dugongidæ.	(Dugong.)

Order V. CETACEA. (Cetaceans.)

Suborder	IX.	MYSTICETE.	(Whale-bone Whales.)
Superfamily	III.	Balænoidea.	(Right Whales.)
Family	XVII.	Balænidæ.	(Fin-back Whale.)
Suborder	X.	DENTICETE.	(Toothed Whales.)
Superfamily	IV.	Delphinoidea.	(True toothed Whales.)
Family	XVIII.	Physeteridæ.	(Sperm Whale.)
	XIX.	Plantanistidæ.	(Gangetic Dolphin.)
	XX.	Delphinidæ.	(Grampus.)

Order VI. INSECTIVORA. (Insectivores.)

Suborder	XI.	DERMOPTERA.	(Winged Insectivores.)
Family	XXI.	Galeoptheridæ.	(Flying Lemur.)
Suborder	XII.	INSECTIVORA VERA.	(True Insectivores.)
Superfamily	V.	Erinaceinoidea.	(Hedgehog and allies.)
Family	XXII.	Tupaiidæ.	(Pentail.)
	XXIII.	Macroscelidæ.	(Elephant Mouse.)
	XXVI.	Erinaceidæ.	(Hedgehog.)
	XXV.	Soricidæ.	(Shrew.)
	XXVI.	Talpidæ.	(Mole.)
Superfamily	VI.	Solenodontoidea.	(Solenodon and allies.)
Family	XXVII.	Solenodontidæ.	(Solenodon.)
	XXVIII.	Potamogalidæ.	(Otter Shrew.)
	XXIX.	Centetidæ.	(Tenrec.)
	XXX.	Chrysochloridæ.	(Golden Mole.)

Order VII. CHIROPTERA. (Bats.)

Suborder	XIII.	MEGACHIROPTERA.	(Frugivorous Bats.)
Family	XXXI.	Pteropodiidæ.	(Flying Fox.)
Suborder	XIV.	MICROCHIROPTERA.	(Insectivorous Bats.)
Family	XXXII.	Rhinopomidæ.	(Tomb Bat.)
	XXXIII.	Emballonuridæ.	(Red Mastiff Bat.)
	XXXIV.	Noctilionidæ.	(Noctilionine Bats.)
	XXXV.	Nycteridæ.	(Nycterine Bats.)
	XXXVI.	Megadermidæ.	(Big-eared Bats.)
	XXXVII.	Rhinolophidæ.	(Horse-shoe Bats.)
	XXXVIII.	Hipposideridæ.	(Nose-leafed Bats.)
	XXXIX.	Phyllostomidæ.	(Vampire.)
	XL.	Desmodontidæ.	(Blood-sucking Bats.)
	XLI.	Natalidæ.	(Natalinæ Bats.)
	XLII.	Furipteridæ.	(Furipterine Bats.)
	XLIII.	Thyropteridæ.	(Funnel-eared Bats.)
	XLIV.	Myzopodidæ.	(Madagascar Bat.)
	XLV.	Vespertilionidæ.	(Long-eared Bat.)
	XLVI.	Myscopidæ.	(New Zealand Bat.)
	XLVII.	Molossidæ.	(Bull-dog Bat.)

Order VIII. RODENTIA. (Rodents.)

Suborder	XV.	SIMPLICIDENTATA.	(Simplicident Rodents.)
Superfamily	VII.	Sciuroidea.	(Sciurine Rodents.)
Family	XLVIII.	Sciuridæ.	(Fox Squirrel.)
	XLIX.	Geomyidæ.	(Pouched Rat.)
	L.	Heteromyidæ.	(Pocket Mouse.)
	LI.	Castoridæ.	(Beaver.)
Superfamily	VIII.	Muroidea.	(True Mice.)
Family	LII.	Muscardinidæ.	(Dormouse.)
	LIII.	Cricetidæ.	(Cricetines.)
	LIV.	Platacanthomyidæ.	(Malabar Mouse.)
	LV.	Rhizomyidæ.	(Bamboo Rat.)
	LVI.	Spalacidæ.	(Mole Rats.)
	LVII.	Muridæ.	(Typical Rats.)
Superfamily	IX.	Dipodoidea.	(Kangaroo Rats.)
Family	LVIII.	Graphiuridæ.	(Short-tailed Dormice.)
	LIX.	Aplodontidæ.	(Sewellels.)
	LX.	Anomaluridæ.	(Scaled-tailed Squirrels.)
	LXI.	Idiuridæ.	(African Flying Squirrels.)
	LXII.	Zapodidæ.	(Jumping Mice.)
	LXIII.	Dipodidæ.	(Jerboas.)
	LXIV.	Ctenodactylidæ.	(Comb-rats.)
	LXV.	Pedetidæ.	(Jumping Hares.)
Superfamily	X.	Bathyergoidea.	(Ethiopian Mole-rats.)
Family	LXVI.	Bathyergidæ.	(Sand Moles.)
Superfamily	XI.	Hystricoidea.	(Hystricine Rodents.)
Family	LXVII.	Hystricidæ.	(Old World Porcupine.)
	LXVIII.	Erethizontidæ.	(American Porcupines.)
	LXIX.	Echimyidæ.	(Spiny Rats.)
	LXX.	Petromyidæ.	(African Rock Rats.)
	LXXI.	Myocastoridæ.	(Coypus.)
	LXXII.	Thryonomyidæ.	(Cane Rats.)
	LXXIII.	Dinomyidæ.	(Giant Rat.)
	LXXIV.	Cuniculidæ.	(Lemmings.)
	LXXV.	Dasyproctidæ.	(Pacas; Agoutis.)
	LXXVI.	Chinchillidæ.	(Chinchillas.)
	LXXVII.	Abrocomidæ.	(Habrocomes.)
	LXXVIII.	Caviidæ.	(Guinea-pigs.)
	LXXIX.	Hydrochoeridæ.	(Capibara.)

Order IX. LAGOMORPHA. (Rabbits and Pikas.)

Suborder	XVI.	DUPLICIDENTATA.	(Leporine Mammals.)
Family	LXXX.	Ochotonidæ.	(Pika.)
	LXXXI.	Leporidæ.	(Rabbit.)

Order X. UNGULATA. (Ungulates.)

Supersuborder	I.	SUBUNGULATA.	(Polydactyl Ungulates.)
Suborder	XVII.	HYRACOIDEA.	(Conies.)
Family	LXXXII.	Procaviidæ.	(Doman.)
Suborder	XVIII.	PROBOSCIDEA.	(Proboscideans.)
Family	LXXXIII.	Elephantidæ.	(Indian Elephant.)
Supersuborder	II.	UNGULIGRADA.	(True Ungulates.)
Suborder	XIX.	PERISSODACTYLA.	(Odd-toed Ungulates.)
Superfamily	XII.	Lophiodontoidea.	(Tapirine Animals.)
Family	LXXXIV.	Tapiridæ.	(Tapir.)
Superfamily	XIII.	Rhinoceroidea.	(Rhinocerine Animals.)
Family	LXXXV.	Rhinocerotidæ.	(Rhinoceros.)
Superfamily	XIV.	Equinoidea.	(Equine Animals.)
Family	LXXXVI.	Equidæ.	(Horse.)
Suborder	XX.	ARTIODACTYLA.	(Even-toed Ungulates.)
Superfamily	XV.	Bunodontoidea.	(Suiform Animals.)
Family	LXXXVII.	Hippopotamidæ.	(Hippopotamus.)
	LXXXVIII.	Suidæ.	(Wart Hog.)
	LXXXIX.	Tayassuidæ.	(Peccary.)
Superfamily	XVI.	Tylopodoidea.	(Camelines.)
Family	XC.	Camelidæ.	(Camel.)
Superfamily	XVII.	Tragulinoidea.	(Chevrotains.)
Family	XCI.	Tragulidæ.	(Water Chevrotain.)
Superfamily	XVIII.	Pecoroidea.	(Cervines.)
Family	XCII.	Cervidæ.	(Deer.)
	XCIII.	Antilocapridæ.	(Prong-horn Antelope.)
	XCIV.	Giraffidæ.	(Giraffe; Okapi.)
	XCV.	Bovidæ.	(Bison.)

Order XI. CARNIVORA. (Carnivores.)

Suborder	XXI.	FISSIPEDIA.	(True Carnivores.)
Superfamily	XIX.	Æluroidea.	(Felines.)
Family	XCVI.	Felidæ.	(Cougar.)
	XCVII.	Cryptoproctidæ.	(Foussa.)
	XCVIII.	Viverridæ.	(Civet.)
	XCIX.	Protelidæ.	(Aard Wolf.)
	C.	Hyænidæ.	(Hyæna.)
Superfamily	XX.	Cynoidea	(Canines.)
Family	CI.	Canidæ.	(Wolf.)
Superfamily	XXI.	Arctoidea.	(Ursines, etc.)
Family	CII.	Ursidæ.	(Grizzly Bear.)
	CIII.	Mustelidæ.	(Weasel.)
Superfamily	XXII.	Procyonoidea.	(Racoons, Coati, etc.)
Family	CIV.	Ailuridæ.	(Panda.)
	CV.	Procyonidæ.	(Racoon.)
	CVI.	Potosidæ.	(Kinkajou.)

Order XII. PINNIPEDIA. (Phocaceans.)

Suborder	XXII.	PINNIPEDIA.	(Finned Carnivores.)
Family	CVII.	Otariidæ.	(Sea Lion.)
	CVIII.	Odobenidæ.	(Walrus.)
	CIX.	Phocidæ.	(Common Seal.)

Order XIII. PROSIMIA. (Lemurines.)

Suborder	XXIII.	PROSIMIÆ.	(Lemurs, etc.)
Superfamily	XXIII.	Lemuroidea.	(Existing Lemurs.)
Family	CX.	Lemuridæ.	(Ring-tailed Lemur.)
	CXI.	Tarsiidæ.	(Tarsier.)
	CXII.	Daubentoniidæ.	(Aye-Aye.)

Order XIV. PRIMATES. (Monkeys and Man.)

Suborder	XXIV.	HOMINIFORMES.	(Hominids.)
Superfamily	XXIV.	Quadrumanoidea.	(Simians.)

3356 EIGHTEENTH STREET, N. W.

THE EARLY SIGNS OF DISEASE OF THE NERVOUS SYSTEM.

By TOM A. WILLIAMS, M.D.,

WASHINGTON, D. C.

DISEASE, even when serious, may fail to be manifested functionally. Familiar instances are chronic nephritis, latent tuberculosis, cerebrospinal syphilis, cerebral neoplasm. On the contrary, function may be disturbed long before we are able by signs to affirm physical disease. As regards the nervous system the first diagnostic issue is the region or structure affected; the second is the etiology or nature of the disease processes. Either of these may be the primary problem to the clinician. When function is disturbed without focal disease of the nervous system the issue lies between disturbance of material source elsewhere or dynamic interference with integration. This latter may be reflex, but is far more frequently psychogenetic, even when the primitive stimulus may be a physical disturbance.

It is folly to attempt to nosologize before formulating these issues, mentally at least. Most of the errors have occurred on account of the premise that when one cannot find physical disease, hysteria is a justifiable diagnosis. Far more pragmatical, at least, is the postulate that when one cannot find a psychogenetic mechanism adequate to account for the symptoms, then physical disease must be present, even although we are unable to elicit its signs. This statement is particularly true regarding pain, disorders of sleep, asthenia, alterations of character, emotional disturbances.

It is particularly frequent, regarding paresthesia, to be asked to examine a patient with a diagnosis of hysteria in whom one finds the characteristic paresthesiæ which occur in the spinal disturbances of pernicious anemia before there can be detected any change in the blood. To ascertain disturbance of the attitude sense is a speedy process to confirm the diagnosis. Many milder cases of encephalitis are labelled neurotic because of the marked changes in character, the slight agitation, the euphoria and insomnia, and the absence of lethargy and paralyses. Frequently in patients sent to me as neurasthenics do I find endocrine disorders, the inertia of hypothyroidism and its headaches. (This is the form of headache which improves during the day in consequence of the stimulus of activity and food and which is so different to the genus of headache which is aggravated by activity, increased by food, or brought on by posture—the toxic or migrainous type which conforms in many clinical characters to the post-commotional headache); the asthenia of hypoadrenia; the agitatedness, irascibility, or fatiguability of mild hyperthyroidism; the indolence and vague feelings of dyspituitarism. Finally, neurotic behavior is often the first sign of a state of mild toxicosis or of an infective focus.

Spontaneous disappearance of symptoms is far from a proof that they are hysterical, indeed it is a presumption that they are not, although asthenia consequent upon emotional disturbance is usually of short duration. Apparent success of psychotherapy is no criterion of hysteria, for symptoms of grave organic disease may be overpowered by suggestion for considerable periods. A glaring example is that of the woman who was kept subjectively well for a year, at the end of which a post mortem showed nephritis, myocardial deterioration, and valvular disease, pulmonary tuberculosis, hepatic cirrhosis, chronic ulcer of the stomach, and carcinoma of the uterus. Ecclesiastical healers have caused thousands of incapables to functionate for a time in the belief that they were healed.

Hence the great danger of confiding patients, even when labelled functional or neurotic, to individuals, even though medical graduates, who are not highly skilled in neurological diagnosis.

This is not to exaggerate the importance of the clinical sign; it can never lose its place, but its superiority as an objective fact should not permit the clinician to ignore the subjective fact set forth by the patient. To do so does not mean the uncritical acceptance at his valuation of every complaint. The complaint is often a mere interpretation, erroneous and fallacious. What we really seek is a subjective fact of the patient's experience, that is a mental fact, a percept, but none the less valid when we know how to shear it of the accretions to which it is so subject, more especially when it is being distorted by friends and perhaps doctors.

1621 CONNECTICUT AVENUE.

RADIUM IN UTERINE HEMORRHAGE.*

By DOUGLAS C. MORIARTA, PH.G., M.D., F.A.C.S.,

SARATOGA, N. Y.

WHEN I told our president that I would have for my subject this evening, the consideration of radium as a therapeutic agent in metrorrhagia, I intended to review the field and give you the conclusions of serious-minded and prominent clinicians concerning the use of radium in specific pathology; and these conclusions I thought to supplement by my personal experience.

While reviewing the literature on the subject, I noted the statement of Dr. John G. Clark of the University of Pennsylvania that 80 per cent of the cases of uterine cancer that had come to this clinic during a period of three years were inoperable. I then reviewed my own notes and found that 100 per cent of the cases of uterine carcinoma that I had seen in my practice during a period of five years were inoperable. As a consequence, I thought a consideration of uterine hemorrhage might prove of interest for a practical discussion. It will at least give us food for thought and an opportunity to explain to ourselves why so many women are allowed to go on without relief to their doom. Many of these women, I grant, bear their crosses uncomplainingly, and do not consult a physician until absolutely forced to do so, and then it is too late. These unfortunate cases can be reached only by educational propaganda.

However, it is not these women that come in for censure, but rather the attitude of our own profession—at least those of us who do not take the initial symptom very seriously, and do not make a diagnosis, and consequently cannot make a prognosis. These practitioners usually putter along with drugs, occasionally temporizing with douches, and usually give some foolish explanation to the patient for

* Read before the Saratoga Springs Medical Society, Jan. 20, 1920.

their failure to relieve the condition. This method, if method it can be called, is continued until it is too late for surgery. The condition is then hopeless, unless, as occasionally happens, radium, caustics, or the *x*-ray effects a clinical cure. If the conditions which I have just stated are as common as they seem to be, some of us are criminally negligent; and this could be surely demonstrated if a malpractice suit should be brought against us on these grounds, for the law exacts "reasonable care and judgment" on our part.

It is obvious, and must be so interpreted, that metrorrhagia is not a disease but a symptom, and one which has for its origin varied pathological conditions. Because of the remote and pernicious morbidity that so often follows this symptom in benign cases, and the great mortality that occurs in malignancy, in which metrorrhagia is the constant early symptom, uterine hemorrhage is the one most important indication which occurs from pathological conditions in the female pelvis, and we *must* appreciate the enormous toll which nature exacts when these conditions are neglected. Just when one is justified in making a pelvic examination in a young girl, or suggesting instrumentation for relief of the symptom, is a determination that must be made in each individual case. But in no instance should the patient be allowed to drift beyond the possibility of surgery.

It is not my purpose to attempt a review of the possible or probable etiology of this symptom, or to suggest procedures for its control; but I do want to say just here, and as emphatically as I may, that the patient ought not to be allowed to go on indefinitely without intelligent advice. And in saying this I fully realize the obstacles which often have to be overcome in the management of these cases; and further, I am sure that they occasionally baffle all the skill of the most clever and experienced clinician. But this is not the point. What I want to call to your attention is the number of cases in which no rational attempt has been made by the physician to determine and control the condition. I feel sure that the suggested discussion of uterine hemorrhage is warranted by the facts I shall give you in the cases which follow.

CASE I.—Mrs. S., housewife, age 52, referred to me for a hysterectomy in June, 1915. She has always been a strong, rugged woman, weighing 160 lbs., never having been ill except at the birth of her three children. She began to flow a year previously and had continued up to the time of consulting me; during this period she had been under the care of two physicians and had taken internal remedies continually; she had also had vaginal douches more or less regularly, all of which were negative in effect. When I saw her, she had lost 30 lbs., was pale, languid, and unable to attend to her customary duties. Red blood count, 3,200,000; white, 6000; hemoglobin, 40. The urine was scanty, contained albumin, on boiling becoming practically solid, and contained small hyaline and granular casts. The tissues over the entire body were markedly edematous. Plainly she was a poor, not to say unjustifiable, surgical risk, and I so advised them. I suggested the use of radium, which was accepted. After the third treatment, the flow ceased, to reappear after 14 months. After two radium treatments it again ceased, and has not appeared up to this time. She entirely recovered her weight, color, and strength, and is now attending to the duties incident to the care of a family of five.

CASE II.—Mrs. R. consulted me in June, 1916, in reference to her flowing which, she stated, had been practically continuous during the past four years; while it had not been profuse, she had been obliged to wear a napkin. She said she had been treated more or less constantly during the four years without material benefit; that her last physician told her she had a tumor which required an operation, but that she was not in a condition to endure it. She was a housewife, aged 58, anemic, easily fatigued on the slightest exertion, legs edematous nearly to the trunk, urine loaded with albumin, with small and large hyaline as well as granular casts. Normal weight 175 lbs.; present weight, 150 lbs. Typical cardio-vascular renal degeneration. On examination I found a fibroid, four inches in diameter, on the right side at the uterocervical juncture. Radium was suggested and accepted, with the result that the hemorrhage ceased and has not recurred up to date (December, 1919); the fibroid has diminished and her general condition has improved somewhat, although the nephritis is about the same.

CASE III.—Miss P., seamstress, age 41, came to me in July, 1918. Was of slight build, had always been regular (menstruation of the 21-day type). Appendicitis in 1913 with perfect recovery. Her sister, a trained nurse, brought her to me for radium treatment, at the direction of Dr. Mount of Albany. Her statement was that she had been all right until a few months previously, when her periods lasted 14 of the 21 days. At her March period she had a severe hemorrhage and her family physician referred her to a Troy surgeon. He promptly curetted her, and she was relieved for a period of five weeks when the flooding again occurred. She returned to the surgeon and he repeated the curettage, this time with a relief of only three weeks. Now, however, the flow was not profuse, though it has been continuous up to the present time. She again saw her surgeon and he advised her going home to be built up, after which he would do a panhysterectomy. It was apparent both to her and to her sister, that unless the cause of the present physical weakness was relieved, not only would she not regain the strength desired for a hysterectomy, but that she was slowly but surely dying (to use her own words). It was at this time that Dr. Mount advised radium. She had lost the little flesh she possessed and was absolutely colorless; pulse rapid and weak, and she tired so easily that it was only with the greatest effort she had been able to come to Saratoga. Kidneys negative. Radium was given, and after the fourth treatment hemorrhage ceased, not to recur. She has improved generally, taken on her former flesh, and well-being, and is now (December, 1919) working steadily at her sewing.

CASE IV.—Mrs. G., housewife, age 41, no previous trouble. She stated that in January, 1919, at a regular menstrual period, she had a severe hemorrhage, so that the doctor was sent for. He came several times, gave her medicine, and she was obliged to go to bed as the flow did not stop. Her husband was advised by the doctor that the condition was due to nervousness, and that he should have her get up and be about or she would be bed-ridden. She did get around the house, was worse, and a second doctor was called. He saw her a number of times, prescribed medicines and a vinegar douche, and after a week told her she should go to the hospital for a slight operation. The flow continued, and a third physician was called. He made, for the first time, a vaginal examination, advised her to go to bed, prescribed internal remedies, and hot douches. The flow diminished, but continued almost constantly until I saw her in August. At this time she was intensely anemic, so pale that she was actually white, and extremely emaciated. Red blood count, 3,000,000, hemoglobin 17. She was practically confined to her bed. Operative interference was out of the question. Radium was suggested and accepted. It was with the greatest difficulty that she was taken to the hospital. Radium was applied, the flow diminished, and ceased after two weeks; it has not reappeared (December, 1919) in excess, although she has menstruated twice since. She has taken on color and weight, and is now able to resume her household duties.

I can appreciate thoroughly the lack of enthusiasm, on the part of the profession, toward the extravagant claims for radium, because it is new and relatively untried, and has not fully come into its

own. However, I do not suggest it as a general panacea, or even that you give it the broad consideration that it has already earned for itself in varied specific instances. But it *is* concededly a specific for uterine hemorrhage. It is easy of application, acts without pain, does not mutilate, and as I have used it in the reported cases, without anesthetics or instrumentation, it has no contraindications. We are all inclined to cling to the advantages of our individual experience, both with remedies and with measures, and naturally so. But I feel that I am justified in pointing out as clearly as I can that radium did control the types of disease that I have presented for your discussion, when the time for the use of the usual remedies had passed.

At present the results of the action of radium, except in uterine hemorrhage, are not uniform; and if they were to be expressed from my own clinical experience, I would say that they consisted of a series of surprising benefits and unexpected disappointments. But this only emphasizes two facts, viz., (1) We do not know definitely all that radium will do, and not always how it does some of the things which it does. But this is not so remarkable when often we do not know the etiology of the pathological condition which we are attempting to treat. I refer to indeterminable uteropathies and malignancy. (2) Only a very small percentage of our cases come early for radium treatment; and in my experience, the suggestion for its use comes more often from the laity than the profession.

But radium has a field and has come to stay. It is not a haphazard measure, by any means. Unfortunately, it is potent for harm as well as for good, when the method of its application and contraindications are not observed.

As you are aware, those most familiar with treating uterine hemorrhage with radium, particularly in patients 35 or more years old, advocate anesthesia, dilatation, and curettage of the uterus. The radium is placed, screened with one or more millimeters of brass, covered with rubber, and this is left in place for 24 hours.

My first case prohibited this procedure, so I used a small carrier made just large enough to hold the glass capsule containing the radium, which was no larger than a uterine sound. This was introduced into the uterus and allowed to remain for two hours. The treatments were repeated every second day. This procedure proved to be so satisfactory that I followed it in the other cases in the series, as they all seemed poor risks for anesthesia. Of course I could not determine whether or not I was dealing with malignancy, nor could I have done differently if I had known.

A possible feature of the therapeutic action of radium was suggested in these cases, *i.e.* its effect on metabolism when used locally. The patients all seemed to convalesce more rapidly than the controlling of the flow would ordinarily suggest. These patients are all alive and apparently normal; case I is 4½ years old, postoperatively; case II, four years; case III, 1½ years; case IV, a few months. In conclusion, I wish to state that I was unable to determine the pathology of any of them, unless case II, which presented a determinable fibroid. Situated as it was, however, it did not seem as if it were the factor causing the hemorrhage.

SKIN GRAFTING.

By HUGH A. BALDWIN, M.D., F.A.C.S.,

COLUMBUS, OHIO.

In spite of its simplicity and desirability, skin grafting is often deferred or neglected entirely, and prolonged convalescence or even deformity results. The theatrical and sensational aspect given to this operation by newspapers is perhaps responsible for the view held by many that it is an operation difficult of accomplishment.

Skin grafting as a practical operation was first brought to the notice of the profession by Reverdin of France in 1869, and his method to-day probably has the greatest field of usefulness. The methods of Thiersch, Wolfe, and Krause are likewise easy of accomplishment and are frequently advisable, especially to bring about the prompt epithelization of wounds made by surgeons in cosmetic or plastic work, when the appearance of the part must be considered. In the Reverdin and Thiersch methods only the superficial layers of skin are used, this being known as epidermatoplasty, while Wolfe and Krause practise dermatoplasty, using the entire thickness of the skin. Grafts taken from the patient himself are known as autografts; if taken from others, isografts or heterografts.

It is with the latter group that this paper most concerns itself. While autografts are undoubtedly the best, the most likely to survive, yet frequently the condition of the patient is such as to render their use inadvisable.

In any hospital there is easily plenty of material for isografts, which can be obtained without subjecting the donor to pain or discomfort. As soon as the area to be grafted is in suitable condition, if the operating-room schedule is watched only a day or two will elapse before some patient with lax abdominal walls will be entered for laparotomy. A Wassermann test should be run; if this is negative, a strip of skin from the sides of the wound can be cut away by the surgeon. This will not be missed by the donor, but on the other hand will perhaps facilitate the closure of the wound. The skin so obtained should at once be transferred to warm salt solution. For ease in snipping off the Reverdin grafts, the skin can be tacked to a board and kept covered with gauze, moist with warm saline solution. The grafts are then cut away, using fine tissue forceps and a sharp knife. Very small grafts can be used, but larger grafts, from an eighth to a quarter of an inch in width and from three-eighths to a half inch in length, are very satisfactory. These should be carefully placed in rows, each graft about an inch from its neighbor. With these larger pieces I try to tuck one corner down into the granulations to prevent possible displacement. After the grafts are in place they are protected by strips of gutta-percha tissue, placed gridiron fashion over the rows of grafts.

One great advantage of this method is that the grafting can be begun on any part of the surface as soon as healthy granulations appear without waiting for the entire area to clean up. These grafts are very resistant and will grow even in the presence of pus.

From personal experience I have found that redundant scrotal tissue, removed in the course of

a varicocele operation, is ideal material. Lucas[1] as quoted by Eisenberg[2] believes that material from these parts possesses a peculiar germinal vitality and advocates the use of a child's prepuce. I have recently tried the latter from new born babes, but failure resulted. The fact that the skin from new born babes is undesirable has been brought out by others, but I am unable to quote the article, as it has been mislaid. That the prepuce of older children can be used has been demonstrated by Eisenberg,[3] who covered the end of a finger successfully with the foreskin removed from the patient, using in this case the entire thickness of skin. The vitality of resected scrotum is shown in a case in which after removing the redundant skin it was put in salt solution and then placed on an ordinary radiator, while the operator went to the opening baseball game of the season. Returning at six o'clock Reverdin grafts were placed on a large ulcer involving a child's abdomen. Every graft took.

Bevan[4] says pessimistically that not more than 10 per cent. of isografts will survive. My own experience would indicate that the percentage is much higher; 50 per cent. or more will adhere and grow if transplanted in the proper manner, at the right time, and with careful after-treatment.

The use of isografts has recently been placed on a secure footing, with the same promise of success as in the case of autografts, by bringing the same principles to bear as in blood transfusion, namely, blood grouping. This principle has been advocated by several men. Its marked advantages have been excellently presented by Harold K. Shawan, M.D., Captain M. C., U. S. A.[4] in an article based on personal experience while with "Lakeside U. S. A. General Hospital, B.E.F." It has been found that all individuals fall into one of four groups depending upon the interaction of mixed bloods. Moss[5] gives the following classification:

"Group I.
Serum agglutinates corpuscles of no person.
Corpuscles are agglutinated by serum of Groups II, III, IV.
Group II.
Serum agglutinates corpuscles of Groups I and III.
Corpuscles are agglutinated by serum of Groups III and IV.
Group III.
Serum agglutinates corpuscles of Group I and II.
Corpuscles are agglutinated by serum of Groups II and IV.
Group IV.
Serum agglutinates corpuscles of Groups I, II and III.
Corpuscles are agglutinated by serum of no person.

Groups I and III are rare groups; Groups II and IV are common. The relative incidence of the four groups, as found by Karsner in 1000 groupings, was: Group I, 3.1 per cent.; Group II, 42.4 per cent.; Group III, 8.3 per cent.; Group IV, 46.2 per cent."

Shawan substitutes the words "skin graft" for "corpuscles" in the above chart and shows most conclusively that the fate of the isografts can be accurately determined by using donors selected according to their blood grouping.

It will be noted, according to Karsner (6), that 46.2 per cent. of individuals fall in Group IV, and can be called universal donors because grafts from this group will grow on individuals of the other three groups, and the chances of selecting such a donor, without testing, would be 46 to 54. Group I comprises 3.1 per cent. and can be called universal recipients, because they will accept grafts from any of the other groups. This brings the percentage of sure takes, without testing, up to 50 per cent., which, as stated in a preceding paragraph, has been my experience. Shawan's conclusions based on twenty-six patients, all grouped by their blood, are as follows:

Initial takes occurred independently of group compatibility; but permanent takes were modified by biological compatibility as follows: Group I patients grew skin from donors of each of the four groups and equally well. Group II grew isogroup grafts and grafts from Group IV, while primary skin takes from Groups I and 111 donors in the course of time either shrunk to minute size or entirely disappeared. Group III recorded only skin from the same group and Group IV as permanent takes. Permanent takes from the same group *only* were obtained in the case of Group IV recipients.

SUMMARY.

1. Autografts grow best.
2. Isografts obtained from donors of the same blood group as the recipient, or from Group IV donors, became permanent takes and grew almost if not equally as well as autografts.
3. Isografts where the donor and recipient were of different groups did not remain as permanent growths except when Group IV skin was used or when the recipient was a member of Group I.
4. Group I recipients grew permanent skin from donors of all of the four groups and apparently equally well.
5. Group IV skin grew permanently on the recipients of all groups, but only Group IV grafts and autografts remained as permanent takes on Group IV recipients.
6. It appears that skin grafting obeys the principle of blood grouping, as in the transfusion of blood.

There are many ways of blood grouping, but the method of Lee[7] as quoted by Karsner[6] is rapid and easily carried out if the standard serums are available. This method is as follows:

From 0.5 to 1.0 c.c. of 0.85 per cent. sodium chlorid solution is placed in a small test tube, into which are dropped two drops of the blood to be tested. If a clot forms, a satisfactory emulsion of cells can be made by shaking the tube. A platinum loopful of each of the standard serums is placed on a clean slide, and into each drop a loopful of the blood emulsion is rubbed. The reading of the agglutination is made under the microscope (16 mm. objective), and is usually complete in from five to fifteen minutes. As will be seen from the table, if both drops show agglutination, the blood is in Group I; if neither shows agglutination, it is in Group 4; and if one shows agglutination and the other not, the blood belongs to the group in which there is no agglutination. A somewhat smoother emulsion may be made by inverting the slide so as to convert the drops into hanging drops. The inverted slide can be placed on the microscope stage and another slide whose ends are built up with small pieces of fairly thick slide pasted on with balsam.

The standard serums can be obtained from the Government Laboratory in Washington. If, however, they are not available the blood of the donor can be tested directly against that of the recipient by any standard method of testing for agglutination. The following method is described by Lee:[7]

One c.c. of blood is collected from the patient and

allowed to clot. The serum is then obtained. One drop of this serum is placed on a slide and mixed with a 10 per cent. suspension of the donor's blood in 1.5 per cent. solution of citrate solution. If agglutination takes place another donor must be sought.

The after care of the grafted area should be under the personal observation of the surgeon and not left to an inexperienced nurse or assistant. The most important feature of this stage is the proper control of the granulations. The granulations must be kept in a healthy condition and maintained on a level with the growing skin. For this purpose nothing can compare with the sticks of fused silver nitrate. Exuberant granulations can be quickly brought back to the correct level by the generous application of the silver while edematous or unhealthy granulations can be stimulated into normal activity by light strokes of the caustic stick.

Beck[8] has recently called our attention to a method by which the granulations are kept even with the skin by the use of adhesive strips. The adhesive plaster keeps the granulations from rising higher than the skin and gives the epithelium a chance to regenerate underneath the plaster, the under surface of the adhesive acting as a path for the regeneration of the cells on the same principle as a vine would grow along a string or a wire. His description of this method is as follows:

> The technic consists in applying strips of plain or zinc oxide adhesive plaster along the edges of the granulating wound. These strips, one-half to three-quarters of an inch in width, must be so adjusted that they cover both margins, that of the skin and that of the granulating wound. This leaves the center of the granulating surface exposed for absorption of the wound secretions by a dry sterile dressing.
>
> Twenty-four hours later the dressing and adhesive plaster are carefully removed. It will be found that along the margin of the skin there has now formed a bluish-gray border, about 2 or 3 mm. in width. This bluish-gray border represents the new growth of epithelial cells.
>
> The wound is now dressed with dry gauze, which is left on for twenty-four hours, followed on the next day by another application of adhesive plaster. This procedure is repeated uptil the entire granulating surface is covered with an epithelial growth.

With small denuded surfaces this method can be used alone with great satisfaction. With large wounds it can be used after grafting as soon as the grafts have become securely attached to their bed. This granulation will cause epithelization to take place with astonishing rapidity.

In this paper no attempt has been made to describe the many maneuvers to be carried out in special or complicated cases. This belongs to plastic surgery, an immense field which is developing into a distinct specialty. I have attempted only to show that the doctor must keep pace with the demand for efficiency and return his patient to work in the shortest possible time with the least amount of scarring or deformity.

347 EAST STATE STREET.

A DISCUSSION OF POST-OPERATIVE RECURRENCES OF ANORECTAL FISTULA, THEIR CAUSES AND PREVENTION.

BY ARTHUR A. LANDSMAN, M.D.,

NEW YORK.

ASSOCIATE SURGEON, RECTAL DEPARTMENT, POST GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING RECTAL SURGEON, JEWISH MEMORIAL HOSPITAL; DEPUTY SURGEON, DISEASES OF THE RECTUM, OUT-PATIENT DEPARTMENT NEW YORK HOSPITAL; PROCTOLOGIST, HEBREW NATIONAL ORPHAN HOUSE.

IN selecting anorectal fistula as the subject of this paper, we have been actuated by the circumstance that the results of the treatment of this disease have not yet reached that degree of perfection which surgeons are trying to attain or patients have a right to expect when they submit to the risks of operation. It is safe to state that in no surgical affection comparable with it, is the prospect of permanent relief more uncertain than in fistula, a statement which may be readily verified by the records of rectal clinics, where naturally the greatest variety of such material is available for study. It is conservatively estimated that 20 to 30 per cent of all persons suffering from fistula have been operated upon for recurrence one or more times, and it is far from certain that some of these will not require further surgery before they are relieved of their symptoms, either because of the return of the disease, or the presence of some complication or sequel which interferes with the orderly function of the parts and with the comfort and happiness of the patient.

Those who are familiar with the natural history of fistulæ, especially with the cases which have been unsuccessfully operated, will concede that while there is a surface similarity among them, they present quite marked difference in their clinical features. According to these differences they may be seen to fall into groups more or less distinct in pathology and clinical course.

GROUP I: Following operation the wound is found to discharge freely, is painful and sensitive to touch, but shows no evidence of unsound condition of its tissues; it may appear to close up entirely, only to be followed sooner or later by soreness and swelling of the parts and the appearance of a discharging sinus; or it may heal over firmly throughout except for a minute opening at one end, from which purulent material may be discharged at intervals. Probing discloses a tract of variable depth which generally will be found to run upwards towards the rectal wall, terminating in a rough, elevated area or in a depression with raised edges.

GROUP II: The wound looks unhealthy, its surface being very faint pale pink, its edges undermined in every direction. Seen before operation, it discharges a dirty grey material through an external opening which is relatively large and

ragged, often presenting a tuft of fungoid granulations. The patient shows an evident lack of resistance, feels weak, and suffers a general deterioration of health.

GROUP III: There is a slight discharge, but little pain and no marked tenderness about the parts. The granulations are delicate and friable, and lack a healthy pink color. Healing is sluggish, delayed or absent, and the scar is bluish and lacks firmness.

GROUP IV: The wound heals uneventfully and the parts look normal. The patient is apparently cured, only to return months or years later with a sinus on the same or opposite side.

GROUP V: In this group belong cases in which the fistula is cured but the patient is not. He is made uncomfortable by constant moisture of the parts, suffers from chafing and pruritus, and often complains of a diminished sense of defecation. He may be unable to control gas and soft stool, or may find it difficult to move his bowels at all except after severe straining.

GROUP I: In this class will be found cases, (a) in which the fistula is of non-specific origin but has numerous branches, one or more of which have been missed at operation; (b) those in which the focus has not been discovered, as may happen in infections originating about the vertebræ, sacrum, coccyx, or pelvic organs; (c) those whose internal opening has not been located and which have thus been treated mistakenly as blind external fistula; (d) rare cases with more than one internal opening in the rectal wall, only a single one of which has been discovered at the time of operation; (e) cases treated without division of the sphincter; (f) and finally these in which, by reason of faulty after-treatment, the tissues have been allowed to bridge over.

(a) To feel reasonably assured that operation for a chronic anorectal fistula will be successful, it is necessary to dissect, divide or destroy all branch tracts, for if any infected tissue is left behind without being properly drained, the chances of recurrence are immeasurably increased. Hence, surgeons have tried various procedures to uncover these, the most common one being the injection of colored fluids such as methylene blue, which stain the tissues and enable the operator to follow the tracts. While this method appears on the face of it sound, practically it has very definite limitations, because of the uncertainty of reaching the smaller tracts, especially when they are plugged with dried products of wound secretion; any excessive pressure may easily force the fluid into the loose cellular fat of the ischiorectal fossa and stain tissue which is uninfected. As the solution colors all tissue alike, there is no way to distinguish those which are pathological, and one may thus actually remove sound portions while leaving infected ones.

A method which has given the writer much satisfaction depends upon the use of sight and touch of the unstained tissue. Infected portions, when wiped clean and dry, invariably show differences in morphology, texture and color, besides imparting to the palpating finger a sense of induration absent in sound tissue. Gentle probing of such areas will readily disclose the direction of any branch sinus; when, as sometimes happens, the parts appear honeycombed with tracts, they are probably dead and are best removed en masse, and the deep layers brought together with one or two catgut sutures.

(b) We suspect that in a few cases of anorectal fistula failure results because the source of the trouble has not been reached. This may originate in traumatism or disease of the coccyx, sacrum, or lumbar vertebra or other neighboring bone, pelvic abscess from suppurative processes of the female genitalia, or the prostate, vesicles, urethre and bladder in the male, broken down gummata, sacrococcygeal tumors, which have become infected and burrow downwards. Unless their focus has been discovered and properly treated, it will be futile to expect permanent relief.

(c) Complete fistula whose internal openings have not been located at the time of operation furnish a considerable percentage of recurrences, inasmuch as these will not heal as long as infective material can enter from the bowel in circumstances which do not allow of free drainage. We are not in sympathy with the suggestion that when one is unable to locate the internal opening of a fistula he may cut into the rectum elsewhere, as that simply opens up additional areas in healthy tissue while making no provision to take care of such as are already infected; neither do we consider it advisable to divide the intervening tissue between the internal and external openings, as we may thus miss a portion of the tract if it does not run through in a straight line. It is safer to introduce the probe from without as far as it will pass, then, with a hooked probe from within the rectum to act as a guide, to dissect upward toward the rectal wall.

(d) Many suggestions have been advanced concerning the treatment of cases which have more than one internal opening, none of which to our mind meets the situation. It seems to be best, if they are on the same side to try, to unite them, precisely as in the treatment of fistula with multiple external openings, for they will nearly always be found to converge toward a main sinus. The management of cases which have openings on opposite sides has been described by the author in *Surgery, Gynecology* and *Obstetrics*, March 1919, p. 276.

(e) Is it necessary to divide the sphincter muscle in operations upon complete fistula? We answer without hesitation that unless this is done we cannot secure good drainage and rest of the parts, conditions which are so essential in the healing of all wounds wherever situated.

(f) The results of the most carefully planned operations may be ruined by slovenly or neglectful after treatment, a truism which applies with peculiar force to the treatment of fistula. The wound must be watched for any evidence of superficial healing before the bottom of it has filled in firmly; if necessary it must be opened up again and again and a layer of gauze inserted into it to keep its edges apart.

GROUP II: This comprises cases which present distinctive features because the local disease is a manifestation of tuberculosis, which dominates the clinical picture. It is unfortunate that they are still spoken of and classified as fistula rather than under their proper names as rectal or perirectal tuberculosis. They generally begin subacutely with mild local disturbances, soon succeeded by a thin, dirty-grey discharge from a wound about the peri-

anal parts which is relatively large and gaping, with thin, bluish edges, and a general appearance of lack of vitality about the skin and subcutaneous tissues which is unmistakable. The question of surgical interference in such a condition presents a serious problem which must be judged by the evidence in each individual case. It depends upon the general condition of the patient, the presence of pulmonary or other complication, the powers of resistance as measured by good appetite, absence of fever and gastric derangement, and slight loss of weight. All things being equal, if the patient's condition permits it we consider it fair to rid him of a focus which might at any time lead to serious complicating lesions elsewhere; especially since operations to that end are short, may be done under local anesthesia, with little loss of blood and but a brief stay in the hospital. On the other hand, if the condition is progressive and the patient shows little resisting power, it is best to abstain from surgical interference, or at most only try conservative measures intended to improve drainage.

GROUP III: Occasionally it will be found that healing of a fistula is delayed or absent in an apparently healthy person despite the most careful attention, while the wound will exhibit characteristics which are not present in normal repair. Such instances occur in patients who suffer from constitutional diseases as active syphilis, diabetes, nephritis, and various blood dyscrasias, and their management goes hand in hand with the treatment of the primary disease.

GROUP IV: It is not uncommon to find persons whose fistula has healed uneventfully and who have been free from symptoms months or years, returning with a recurrence on the same or opposite side. By the frequency with which such instances come under observation, we are persuaded that this is more than a mere coincidence. We saw two cases recently in which the patients returned with evidence of acute infection at the site of the old wound over ten years after operation, having been entirely well during the interval, as far as they knew. There is little question from the evidence at hand that this is due to an increased vulnerability of parts weakened from infection, producing loss of local resistance, rather than true recurrence.

GROUP V: Every surgeon is familiar with the patient who long after his fistula has healed has a variety of annoying if not serious complaints referable to the rectum. To set such persons down as neurasthenics without carefully considering all possible sources of local trouble is unfair, certain to invite disaster. Chafing and pruritis may arise in such circumstances from irritation of a thick scar in which peripheral nerve endings have become imprisoned, and should be treated by prophylaxis, such as early operation to prevent excessive scar formation, blocking out as much of the cicatrix at operation as possible, and bringing the deeper portions of the wound together by catgut sutures, in order to diminish the amount of scar tissue to be filled in by repair. When seen after operation dilation of the sphincter offers a chance of improving the symptom. An annoying post-operative complaint following fistula operations consists in the diminution or loss of the usual desire to empty the bowel; the patients go to stool because of the dictates of their judgment and not because they are conscious that there is an accumulation of stool. On the development of such symptoms, strange to say, people sometimes forget to empty the bowel until a mild form of actual impaction is produced, and we have one such case on our operative records. When this occurs as a post-operative condition it is ascribed to an interruption in the peripheral nerve conduction due to the cutting of the nerves, their destruction by disease, or imprisonment in unyielding scar tissue. Fortunately, this is not a permanent condition but subsides when the nerves have become regenerated. More serious is the inability to control gas and soft stool which follows when there has been extensive abscess formation with destruction of portions of the sphincters and the levator ani; when they have been cut improperly, and when both internal and external sphincters have been divided in one or more plane. The levator ani, though not generally classed as a sphincter, performs an essential function in the control of the stool, which it is enabled to carry out most efficiently by encircling the walls of the rectum in a situation where the effect of leverage is greatest. It would be strange indeed from what we know of the reserve forces which are exhibited everywhere in the human body, if nature were to trust a function, whose loss spells chronic invalidism, to two muscles, one of which is a little slip no thicker than the blade of a small pocket knife, the other really not a true sphincter at all, but a thickening of muscle fibers which have no fixed points from which to work. No, the hand work of God shows no such fatal omissions. The best union between the cut ends of a muscle is secured obviously when all of its fibers are made to unite, which can best take place after a division of it at right angles; if they have been severed obliquely there is a tendency for the unsupported lower strands to retract and become lost, union occurring only in the median plane, and resulting in weakened control of the outlet. When both sphincters have been thus injured, and when the injury has taken place in more than one plane, it is evident that the risk of incontinence is correspondingly increased.

All operations upon the anal canal lead to a certain amount of narrowing of an outlet which at best is none too large, and requires careful watching for undue contraction. When the pathology which calls for operation, results in loss of substance which must be replaced by scar tissue, it becomes obvious that one must be prepared to meet the functional disability corresponding to such loss. In the case of fistula which has been preceded by extensive abscess, such loss may be considerable; if no large abscess has occurred, but the fistula existed a long time before an attempt has been made to excise it, repeated exacerbations take place, each of which is followed by loss of muscle tissue and replacement by inelastic scar, leading to a narrowing of the outlet sometimes amounting to true stricture. The remedy of this serious condition lies largely in prevention, and the application of such approved surgical measures as are readily carried out if patients can be made to see the situation and submit to proper treatment before permanent damage has been inflicted upon the parts.

310 WEST EIGHTY-SIXTH STREET.

Medicolegal Notes.

Degree of Skill Not Limited to Locality in Missouri Courts.—The Missouri Supreme Court holds that an instruction to the jury in a malpractice action that in performing an operation it was the defendant's duty to exercise reasonable skill and care, such as an ordinarily skillful and careful surgeon is accustomed to exercise and use in like surgical operations under like circumstances, is proper, and should not be limited to "the degree of skill possessed by reasonably skillful surgeons in the community" in which the defendant is practising."—Krinard v. Westerman (Mo.), 216 S. W. 938.

Causal Relation Between Accident and Pneumonia Not Known.—A salesman for a firm of wholesale fish dealers lifted a heavy box of goods weighing about 200 lbs., and while doing so felt his back snap and felt a very severe pain. He complained of this and from the time it happened gave evidence in his movements that he had sustained an injury. He remained about the place of business a short time and then went home and called a physician, who strapped his back. The doctor visited him professionally a number of times. Later pneumonia set in and the patient died about three weeks after the accident. The New York State Industrial Commission holds that while it was evident that the deceased had received an injury in lifting the heavy box, it was impossible nevertheless to make a finding under the circumstances of the case that there was any causal relation between such injury and the conceded septic pneumonia and pharyngitis which was the cause of death. Award under the Workmen's Compensation Act was therefore denied.—Meigs v. Robins & Robins, 21 State Dep. Reps. 389.

Statements in Proofs of Loss on Accident Policy—Use in Hypothetical Questions.—In an action on an accident policy three physicians testified as experts, in answer to a hypothetical question, that, in their opinion, the deceased's condition and subsequent death resulted from some external violence, some injury. The hypothetical question propounded to these physicians contained some facts pertaining to discoveries at the operation performed on the deceased, gleaned from the attending physician's certificate attached to the proof of loss, which, being *ex parte*, were only competent for the purpose of showing a compliance with the terms of the policy. The Indiana Appellate Court holds that, the certificate not being competent against the insurance company to prove any facts therein, these facts, unless otherwise proven, should not have been included in the hypothetical question.—Abendroth v. Fidelity & Deposit Co. (Ind.) 124 N. E. 714.

Powers of North Carolina Board of Chiropractic Examiners.—Under statute passed in 1917, and amended in 1919, the State of North Carolina provided for a State board of chiropractic examiners to be composed of three practising chiropractors of integrity and ability, resident in the State, which board was given certain supervisory powers on the subject, including the licensing of practitioners therein, etc. Certain exemptions in regard to examination were allowed to those already in practice. The North Carolina Supreme Court holds that where the evidence before the board as to whether the applicant for license had been engaged, as claimed, in the practice of chiropractic prior to January 1, 1917, entitling him to license under the statutes, was conflicting, the court will not control the board's exercise of its powers to pass on the bona fides of the applicant's claim; and upon the board's refusal to grant a license on the ground that the applicant had not been so practising, will not by mandamus direct issuance thereof.—Hamlin v. Carlson (N. Car.), 101 S. E. 22.

Transference of Streptococcic Infection from Foot to Face.—The California Supreme Court holds that a finding of the Industrial Accident Commission that a streptococcic infection in an injured toe was transferred to the face of the deceased employee by external means, and that the death was proximately caused by the original injury, giving him erysipelas and septicemia, being based on the testimony of medical experts grounded on medical science, cannot be overturned. The medical testimony on which the commission based its finding that the germs which caused the facial infection were carried from the toe to the face by external means was, in effect, that such a method of transfer was exceedingly common, the transmission of the germs being very readily accomplished, that there was no reason to suppose that the infection had come from another source than the toe, and that, while it was within the realm of possibility for the infection to have come from another source, such hypothesis was so very much the least probable that it seemed useless to theorize as to such possibility in the face of facts indicating that the germs "certainly must have been carried" from the foot.—Bethlehem Shipbuilding Corp. v. Industrial Acc. Com. (Cal.), 185 Pac. 179.

Right to Practise a Valuable Property Right—Powers of Board of Medical Examiners to Suspend Licenses.—The California Board of Medical Examiners suspended the license of a physician for one year, whereupon the physician began a proceeding in the Superior Court to review the action of the board on the ground of excess of jurisdiction. From a judgment of the Superior Court sustaining a demurrer to his complaint, he appealed, on three grounds: (1) That the provision of the statute empowering the board to suspend or revoke a license to practise medicine, upon finding the practitioner guilty of "unprofessional conduct," is unconstitutional; (2) that the complaint filed with the board did not sufficiently state any cause for the revocation or suspension of the license; (3) that no sufficient evidence was produced on the hearing before the board to prove the charges or justify the suspension. The power given to the board to revoke or suspend the license of a person duly admitted to practise medicine, upon finding him guilty of charges of unprofessional conduct, as defined in Section 14 of the statute, is judicial in its nature. And the right to practise medicine is, like the right to practise any other profession, a valuable property right, in which one is entitled to be protected. Nevertheless, it is now well settled in California that tribunals such as the board of medical examiners or other boards empowered to revoke licenses which they have previously granted, for cause defined by the law, are not courts in the strict sense; they are not exercising "the judicial power of the State" as that phrase is used in the Constitution conferring judicial power upon courts, and that statutes creating such boards and conferring such powers upon them are constitutional. It is also settled that, where a board has exercised quasi judicial power of the nature of that in question, its decisions are subject to revision by certiorari. The complaint charged the procuring a criminal abortion upon a pregnant woman, naming a certain person. The plaintiff contended that the board could not have jurisdiction unless the charge was as specific and complete as would be necessary to an indictment under the provisions of the California Penal Code defining the crime of abortion. In support of his point that there was no legal evidence to support the decision of the board, his claim was that the charges were sustained wholly by the testimony of persons who would in a criminal prosecution have been classed as accomplices in the act charged, and that under the Penal Code no conviction could be had on the testimony of accomplices alone. Neither of these contentions was sustained, the first, because the complaint need not be specific, and the second because the board is not limited to the rules of evidence prescribed by the Penal Code. The judgment was affirmed.—Luckow v. Board of Medical Examiners, California Supreme Court, 187 Pac. 965.

Propriety of Allowing Hypothetical Question Rests with Court.—The propriety of allowing hypothetical questions rests largely in the discretion of the trial court, and, where such questions are allowable, it is the duty of the trial court to see that they are properly framed, that they are responsive to the issues in question, and that they assume only such facts as are supported by some evidence in the record. Whether such facts have been actually proven is a question for the jury to decide. But the party framing such questions should be allowed a fairly wide latitude, so long as he keeps within reasonable bounds as to his theory of the case and the evidence supporting such theory. The opposing party has the right to rebut the facts assumed, as well as the testimony of the witness.—Dean v. Seeman, South Dakota Supreme Court, 176 N. W. 649.

CARTILAGE GRAFTING.

THIS subject receives a complete historical and periscopic discussion by Mauclaire in *La Presse Médicale* for Aug. 11, 1920, xxviii, 56. It begins with the work of Middeldorph in 1852 in animal experiment. The first work in connection with mankind was reported by Koenig in 1896, who was closely followed by several of his German colleagues. It is advantageous to relate the animal and human researches individually. Middeldorph placed a bit of cartilage in the peritoneal cavity of an animal and it was absorbed. This was an autoplastic graft. Ollier announced in 1857 his opinion that for a graft to take, the perichondrium should accompany the cartilage. We hear nothing further until 1877, when Zahn implanted the cartilage of an animal under its skin and elsewhere, and employed adult homoplastic grafts. These underwent fatty degeneration, but when embryonal cartilage was used the grafts took in an artificial cavity with good blood supply. One year later Tizzoni showed that a graft could survive in a joint cavity. The author now traces the subject down to near date and sums up as follows: cartilage has low vitality and the least pus formation in the recess for the graft means necrosis. After the introduction of antisepsis and asepsis the experiments succeeded more frequently. Grafts in the peritoneal cavity and under the skin where no useful purpose can be served undergo atrophy and a so-called "active graft" which can exert some function of a mechanical character has a better chance of survival. A pedicle and a good vascular supply are conditions which make for survival. Homoplastic grafts from one dog or rabbit to another are often successful. Nageotte had a positive result with auricular cartilage from a dead rabbit implanted into the ear of a living rabbit. Heteroplastic grafts have in general failed.

Human grafting of cartilage inaugurated by Koenig first consisted in the closure of a tracheal fistula by thyroid cartilage. Next a series of grafts were made by German surgeons with costal cartilage used for the closure of tracheal and laryngeal fistulæ in a two-stage procedure, in the first stage of which the fragment was implanted from the nearest cartilage under the integument, while in the second it was made to close the fistula. Rhinoplasty was effected in the same fashion. Numerous cases of analogous character followed, and in 1907 the author implanted a piece of costal cartilage into a defect in the subject's tibia due to osteomyelitis. At a later period Morestin sought to close cranial defects in a similar manner, but the process was not really grafting for the fragments simply became encysted. Cartilaginous grafting for occlusion of defects with costal and auricular cartilage has become too frequent to quote and has been chiefly autoplastic. Results with homoplastic growths have been dubious, while heteroplastic growths have always failed.

The author now takes up grafting with articular cartilage in animals and mankind. This comprises transplantation of articular cartilage with bone, arthroplasty, etc., but this sort of cartilage has also been used in filling defects in long bones. He distinguishes between conjugal and diarthrodial cartilage. The work done in this field involves transplantation of bone with its articular surfaces, as when a fibula is used to replace an exsected ulna, in whole or in part. Generally speaking, grafts with conjugal cartilage used largely in animal experiment have not made good in mankind while autoplastic diarthrodial grafts often succeed; homoplastic grafts have succeeded while heteroplastic grafts absorb. Homoplastic grafting is done under difficulties and the transplants must be conserved with ice.

SCLEROSIS OF THE FACIAL GLANDS.

UNDER this title Portmann describes in the *Journal de Médecine de Bordeaux* for August 10, 1920, xci, 15, the affection commonly known as Mikulicz's syndrome, which is not believed in some quarters to be an autonomous disease. He first describes in full two cases of different type from the original affection (first described in 1892 by the Breslau surgeon). In the type case the disease began in the lacrymal glands and was seen by an ophthalmologist; other cases first developed in the salivary glands, but whatever the debut the patient soon presented enlargement of both kinds of gland. Patients complained of defective sight and inability to masticate, the mouth becoming habitually dry. Gradually it was noted that the ordinary mucous glands of the mouth could participate. Not until 1909 were the atypical forms thoroughly understood, and about this time a relationship with some of the leucemias was seen and the opinion was divided as to whether they had to deal with a pseudoleucemia or a form of tuberculosis. Later it was regarded as an endocrinic disorder comparable to exophthalmic goiter, etc. But whatever component thus came to the front, it was always absent in the average case. In 1912 it was found as a gonorrheal metastasis and later Frenkel found physiological types in which no pathology entered. These were naturally mild and abortive. Much symmetry in evolution and appearance, benign type of evolution, and absence of blood changes speak for a physiological affection. Of the pathological forms the causal factors may be simple adenitis, tuberculosis, syphilis, the causes of the

leucemias and pseudoleucemias, etc. Not much attention has been paid to the sclerotic forms or stages of the syndrome.

Studied from the latest viewpoints the author's two cases are instructive. Along with some hypertrophy other structures presented only atrophy. Thus in one subject only the parotids were hypertrophic, the other salivary and lacrymal glands being sclerotic with total suppression of function. In the other patient the nasal glands participated along with the salivary, the lacrymal glands being but slightly involved. There was nothing to show that sclerosis had been preceded by hypertrophy, and apparently the sclerotic component had never entered into the conception of Mikulicz's syndrome. It was believed certain that any of the glandular structures in the face, superficial or deep, could undergo this sclerosis, with or without some hypertrophy. The conception of the syndrome must therefore be greatly enlarged to include the atrophic manifestations, and if the condition is truly autonomous, with some constant causal influence, the author can only suggest some alteration in the trophic nerves of the face.

MAY GRIPPE BE TRANSMITTED BY THE FLEA?

THE author, Gaminara, whose article is found in the *Anales de la Facultad de Medicina de Montevideo* for May-June, 1920, v., 5-6, does not, of course, necessarily mean that such a method of transmission is the rule, but merely asks if such transmission is possible or does occur. Dr. G. Friedman of New York asked the same question about the bedbug in the MEDICAL RECORD at the time of the pandemic, and similar queries have been put from time to time. The present author, however, writes at great length on the subject. Unless there is aerial contagion, he says, it is difficult to comprehend some things about the great pandemics and their relation to *influenza nostras*. Concerning interhuman transmission we know some things, such as contagion by nasal secretions, but in many cases the transmission seems to have been not so direct, but indirect, although we know nothing in this connection of fomites and animal transmission. Not the author himself, but his friend, Dr. Diaz, first conceived the possibility of flea transmission. The influenza was essentially a sepsis and the flea bite might explain how the blood could become so quickly contaminated. The author in this connection appeared to have overlooked the fact that one of the most certain criteria in the differentiation between pandemic influenza and bubonic plague was the absence in the former of any suggestion of flea transmission, but later in his study he comes to this point and makes it serve him as an argument for instead of against flea transmission. In fact he believes that the flea is responsible for the great points of similarity between the two pestilences. He goes back before the pandemic to some remarks made by the medical men of the Pasteur Institute of Constantinople, who thought that flea transmission explained not only the bubonic but the pneumonic form of the old plague. But the fact of the complete protection of Japanese medical men and others when in attendance on victims of the lung plague by the face mask would seem to nullify this doctrine. It might, of course, be answered that an energetic flea prophylaxis was in vogue at the time, and one might also adduce in this connection the failure of masks in other cases.

Many instances are quoted in connection with the late pandemic and its echoes which are explicable by the theory of flea transmission, but which do not exclude the likelihood of other methods, nor does the author seek to belittle the ordinary modes of communication of the disease. Thus certain victims without exposure to others noted the great abundance of fleas before they were stricken. Important in this connection is the fact that the flea accused for influenza is the human and not the rat or another flea. The author also submits facts about fleas in connection with the pandemic of 1890, and believes that he has at least proved that so far as Montevideo is concerned there was almost a plague of these insects in both pandemic years. In numerous cases people who had not been flea bitten before came down with grippe in from 24 to 48 hours after having been bitten as shown by the marks of the insect. Medieval writers made the same observation about the transmission of the plague. It may be possible for the flea to cause plague sepsis without any formation of buboes as contended by Symond in 1910 or 1911, and it may, of course, be possible that influenza is thus transmissible, but the author has not made his case very convincing and his ideas are probably shared by few.

STANDARDS OF INTELLIGENCE.

HUMAN beings differ not only in the knowledge that they have acquired, but in their dower of intelligence or general ability. It has long been accepted that the former property may continue to increase until the natural faculties begin to abate, but that the latter has a maximum for each individual, attained early in life. It has been suggested, even, that the physical structure of the brain gives visible testimony to these mental differences, the branching processes of the cells being the correlate of the results of education, the actual cells being a measure of the natural endowment. The ramifications certainly increase during life, while the cerebral cells do not multiply, although they take some time to reach maturity. The histological structure of the cerebrum, even if it be correctly interpreted, can be taken as no more than a rough diagram of the mental phenomena, but it serves to illustrate the observed fact that intelligence, as opposed to knowledge, is fully developed before the age of schooling is complete. Sixteen years has usually been taken as the age at which, even in those best endowed, the limit of intelligence has been reached. Obviously the standard varies from one subject to another; the degree of intelligence passed through by the more fortunate at the age of ten may be the

final attainment of others, and all intermediate stages occur.

During the late war the United States faced the enormous task of creating a modern army in the smallest possible time, and the aid of psychologists was enlisted to examine and classify the intelligence of recruits so as to marshal these men into the places for which they were the most fitted. Ingenious and rapid tests of intelligence were devised, and were applied to one million seven hundred thousand cases. This was a fair sample of a population roughly estimated at one hundred millions, and a larger scale examination than had ever been before attempted. Mr. H. H. Goddard, the well-known psychologist, thinks himself justified in taking the army sample as a fair criterion of the entire population of our country. He classifies the intelligence of our male population into seven grades, but believes that in exceptional instances, amounting to four and a half per cent. of the population, a superlative standard of intelligence is attained at the age of nineteen years. On the other hand, seventy per cent. of the citizens of the United States are compelled to carry on their lives with the intelligence of children of fourteen years, and ten per cent. with that of children of ten. These curious results should have a deep intrinsic interest to all students of human nature, and they are of direct importance to the art and science of education, an all-important side issue of medicine.

Rapidly Fatal Poisoning by Phosgene.

Irene Gerber of Geneva, assistant to the medical clinic of the University, reports this case in the *Revue médicale de la Suisse romande* for June, 1920, xl, 6. The victim was a chemical engineer aged 29, admitted to the clinic September 19. His previous condition had been good and he was robust of habit. Two years before he had been poisoned with nitrobenzol and had severe dyspnea and cyanosis; but in 24 hours these symptoms were dissipated by the use of oxygen and after a month's interval he was back at his work. His recovery seemed to have been complete and he was not again exposed to any poisonous substances until he began to handle phosgene in an ether-ethyl-chloroform synthesis. The gas is set free in a certain quantity during one of the manipulations and some of the workmen had been temporarily incapacitated by the fumes. The victim had not been exposed longer than the two laborers and he complained only of irritation of the eyes and a cough as he turned to the clerical duties of the laboratory. He was so preoccupied that he neglected to go to supper and instead took a drink. His bad appearance was noted by others and he was sent home. He collapsed before reaching his dwelling and was sent to the hospital with the correct diagnosis. Here he was seen to be cyanotic over the entire body and received oxygen inhalations, camphor injections, etc., but death took place 34 hours after the exposure. The clinical history and autopsy finds are given *in extenso*. That one should suffer death while the two others were only incapacitated for the day by the same exposure was confusing, and caused the suspicion of some mixed intoxication, but the possibility of any other factor, such as inhalation of nascent hydrochloric acid seems to have been excluded. There is left the possibility of the formation of the acid from phosgene in the parenchyma of the lung with production of a second and fatal stage; the two workingmen having experienced only the first stage.

Accidental Amenorrhea.

Under this title Dalché contributes a paper to the *Gazette des hôpitaux* for July 6-8, 1920, xciii, 60. He makes three types, due respectively to exposure to cold, traumatism, and emotional shock. Amenorrhea in this connection refers to suppression of the function either at its onset or during its course. Cold as a cause is sufficiently familiar. In certain cases one suppression has been followed by life long invalidism. The exposure may be slight as when suppression follows simple washing of the hands in cold water. Chilling of the feet or legs may be sufficient, and one of the simplest methods of arresting flooding is to place the feet in cold water. Of the traumatic form the author says but little and mentions suppression as a result of railway accidents. The mechanism is obscure and perhaps these cases are best placed under the rubric of mental shock, which reduces the number of familiar types to two. The author goes extensively into the subject of emotional amenorrhea and cites interesting cases. This form may produce its effect in the intermenstrual period. During the bombardments from the air, suppression occurred from fright and one such case in a robust young woman appeared to set up hysterical pseudomeningitis; however, the fatal ending led to an autopsy, when it was learned that the patient had succumbed to tuberculous meningitis. It was believed that the sudden suppression had mobilised the tubercle bacilli in some latent focus. The phenomenon known as emotional anaphylaxis is seen in this connection as when a subject as a result of some passing emotional experience becomes sensitized to the cause of the emotion; in such a case repetition of this mild emotional experience may provoke suppression. Among the serious results of sudden suppression may be mentioned ovarian apoplexy and catamenial internal bleeding.

The Irish Fasters.

Laumonier writes on the subject of fasting in the *Gazette des Hôpitaux*, Sept. 14-16, 1920, xciii, 79. There have, he states, always been fasters, and we have professional fasters, such as Succi, Merlatti, Tanner, and Cetti. Tanner by the way lived to be 91, which speaks well for his good constitution and for the harmlessness of his fasts. The limit in professional fasting—and this species must stop in season to save life—is considered about 50 days. The insane faster has beaten this record, and Devillers reported a fast in an insane man of 76 days. It is not stated whether or not this man survived the experience but it is to be presumed that he died. The type of hunger striker is different in some respects. He may expect to yield or be forced to eat, or persists in a hopeless case until death. If the hunger striker hopes to sur-

vive he must be guided by the practice of the professional, taking water freely and keeping as nearly motionless as possible. An important factor in hunger striking is the *morale*. The subject is calm and fears nothing, so that his condition is the opposite of that of the man trapped in a mine or the shipwrecked sailor. The insane faster does not fret about himself, and the lethargic or hysterical faster being in a trance-like state is also free from worry. The latter seems a powerful factor to shorten life in fasting. In professional fasting the great suffering is usually assuaged with opiates and doubtless these have been used for the Irish fasters who are said to have suffered greatly. The temperature goes to subnormal but does not sink beyond a certain level until the final descent, which is called a fatal prognostic if not heeded. Yet Cetti, who according to Zuntz paid no attention to this terminal fall, hungered on and recovered.

Weil's Disease.

A certain amount of confusion is likely to arise in regard to spirochetosis icterhæmorrhagica because the Teutons do not appear to be inclined to give up the term Weil's disease and raise questions of unicism and dualism. Sobernheim at a session last winter of the Medical Society of Berne (*Schweizerische medizinische Wochenschrift*, July 8, 1920, i, 28) read a paper on Weil's disease. The clinical and autopsy pictures show marked polymorphism. In asserted ignorance of the Japanese labors, Germans claim to have discovered the transmissibility of the disease in the laboratory during the year 1915. They found a parasite the nature of which for a time was obscure but later it was named *Spirochæta nodosa*. Quite independently other German pathologists discovered a spirochete which they termed the *S. icterogenes*. The latter was cultivated successfully. Only recently had the author had the opportunity of seeing the Japanese preparations of icterus hemorrhagica and its spirochete and of comparing them with the German finds. So far as he had gone he was by no means satisfied that the two affections were identical and he proposed to deal with this problem forthwith. The two spirochetes show points of difference and in animal experiments the Japanese seems the more icterogenic and the German the more hemorrhagic. Apparently Sobernheim would temporarily call the Japanese disease "seven-day fever" and the German malady "Weil's disease."

News of the Week.

International Health Board Widens Scope.—The annual report of the International Health Board of the Rockefeller Foundation, recently issued, outlines plans for a campaign against hookworm disease and yellow fever in new parts of South America and China, and reviews its work since its establishment in 1914. It dwells particularly upon the enlargement of the cooperative plan of the board during 1919. All the work of 1919 was conducted in close association with governmental agencies.

Guayaquil Free From Yellow Fever.—According to the report for 1919, recently issued by the International Health Board of the Rockefeller Foundation, the last health campaign conducted by the late Major General William C. Gorgas was a success—Guayaquil, Ecuador, is free from yellow fever.

"Youth" for Sale.—American financiers and Physicians, according to press notices, have formed a million-dollar company in Vienna for the purpose of founding an establishment for "juvenescence by the Steinach method."

Eight Millions Asked by League of Nations for Fighting Typhus.—The League of Nations News Bureau, reviewing a report recently received from the Secretariat of the League, states that the League, through its Typhus Commission, has asked its members to contribute eight millions of dollars for fighting typhus fever in Poland and for protecting the rest of the world from a general spread of the infection. In Poland and Galicia cases of typhus have increased from 34,538 in 1916, to 231,206 in 1919. The estimated number for 1920 to date is 306,000.

Red Cross Aids Italian Earthquake Victims.—Relief supplies of an approximate value of $135,000 have been donated by the American Red Cross for the sufferers from the recent earthquakes and tornadoes in Italy. Practically 25,000 people are said to be homeless, having lost everything they possessed. Seven villages, each with a population of 2,000, have been completely destroyed. An outbreak of typhoid fever has given an added horror to the situation, causing many deaths.

Vienna Cardiologist Accused of Cruelty to Conscripts.—Professor Wagner von Jauregg, cardiologist of the University of Vienna, who recently appeared before a commission investigating war delinquencies, is charged with cruelty in the use of a high electric current to detect "heart disease shammers" among conscripts. It is said that several deaths resulted from his treatment, while a number of men committed suicide because of the suffering thus inflicted.

Professor Magnus Hirschfeld, noted German physiologist, who was reported to have died in a Munich hospital as the result of bodily injuries inflicted by anti-Semites, is now said to be alive, having recovered sufficiently to leave the hospital.

Institute on Red Plague Diseases.—The United States Public Health Service has organized an institute on venereal disease control and social hygiene to be held in Washington, November 22 to December 4. At this meeting health officers, private practitioners, clinicians, educators, psychologists, sociologists and others who feel the need of further information in regard to the twin diseases of the red plague and in regard to the different sciences that have helped in building up our now wide knowledge concerning them, may obtain, free of all charge, the benefit of ten days' intensive training by the best experts, man and woman, in the country. In this work the American Social Hygiene Association and the Interdepartmental Social Hygiene Board will assist. The session of the Institute will be followed by the All-American Conference on the Great Red Plague, which will continue for six days.

Hospital for Shell-Shocked Soldiers.—The new

Government hospital at Perryville, Md., where the U. S. Public Health Service will provide special care and treatment for shell-shocked soldiers, was opened recently with the transfer of over 100 patients from the temporary hospital at Cape May, N. J. The new institution is in charge of Surgeon E. H. Mullan, an experienced regular officer of the Public Health Service, who has been the commanding officer at Cape May. At the present time the Public Health Service has under treatment over twelve thousand discharged soldiers suffering from shell-shock and other mental disorders. Of these 5,578 are in hospitals operated by the service, and the remainder in other hospitals where proper care and treatment is provided under contract.

Training of Industrial Cripples Urged.—Philander P. Claxton, United States Commissioner of Education, at a recent conference of state directors and officials of the Federal Board for Vocational Education, said every state in the Union must make provision for the maintenance of industrial cripples if proposed plans for their rehabilitation are to be successfully executed. It is planned, he said, to spend $7,000,000 on vocational education, in the rehabilitation senses, during the next two or three years.

Pharmacologist Needed.—The United States Civil Service Commission announces an open competitive examination for pharmacologist, to fill a vacancy in the Bureau of Internal Revenue, Treasury Department, Washington, D. C., at $2,500 to $3,000 per year. Vacancies in positions requiring similar qualifications, at these or higher or lower salaries, may be filled from this examination. Applications should be made before November 30, on Form 2118, obtainable from the United States Civil Servcie Commission, Washington, D. C., or from the Secretary of the local United States Civil Service Board.

"Protective Social Measures" Workers Wanted.—The United States Civil Service Commission announces open competitive examinations for the following: Director of Bureau, Division, or Section of Protective Social Measures, $3,500 to $4,500 a year; Supervisor of Protective Social Measures, $2,800 to $3,600 a year; Field Agent, Protective Social Measures, $1,800 to $2,000 a year; Special Assistant Agent, Protective Social Measures, $900 to $1,500 a year. Vacancies in the United States Interdepartmental Social Hygiene Board, for duty in Washington, D. C., and in the field, at the salaries indicated, and in positions requiring similar qualifications, will be filled from these examinations, unless it is found in the interest of the service to fill any vacancy by reinstatement, transfer, or promotion. Applicants should apply before November 23, for application form, stating the title of the examination desired, to the Civil Service Commission, Washington, D. C., or to the secretary of a local United States Civil Service Board.

New York State Civil Service Positions.—The Civil Service Commission of the State of New York announces the following appointments to be made:

Assistant Medical Officer, Office of Health Officer, Port of New York. $1,800. Candidates must be licensed physicians. The appointee must reside at City Island and give part of his time to the inspection of vessels from foreign ports, and the examinations of passengers and crews for the detection of the quarantinable diseases, such as cholera, plague, typhus fever, yellow fever, smallpox, and leprosy. No written examination will be required, but candidates will be rated on training, experience, and personal qualifications. Inquiry may also be made as to character and ability and all statements are subject to verifications. An interview may be required.

Coroner's Physician, Monroe County. $200 a year. Candidates must be licensed physicians. No written examination will be required, but candidates will be rated on training, experience, and personal qualifications. Inquiry may also be made as to character and ability and all statements are subject to verification. An interview may be required. This position requires part time only.

Professor Jules Bordet, director of The Pasteur Institute of Brussels, will deliver the second Harvey Society Lecture at the New York Academy of Medicine, Saturday evening, October 30, 1920. His subject will be "Coagulation of the Blood."

Dr. Charles Mallory Williams has removed his office to No. 4 West Fiftieth Street.

Dr. John Rogers has removed to 177 East Seventy-first Street.

Tuberculosis Christmas Seal Campaign.—Plans are being formulated by the County Tuberculosis Committees of the States Charities Aid Association. The campaign is scheduled for the month of December, during which time it is planned to raise the State's quota of $582,000, exclusive of New York City.

Birth Control Endorsed by Women's Clubs.—The New York State Federation of Women's Clubs, at its twenty-sixth annual meeting recently held at Utica, placed itself on record as favoring birth control.

Ocean Liner Made Quarantine Boat.—When the Holland-America liner *Nieuw Amsterdam* arrived from Rotterdam last week, with 621 cabin and 1,673 steerage passengers, it was found that a boy from Czecho-Slovakia had developed smallpox during the voyage. The first and second cabin passengers were vaccinated and allowed to land, but the steerage passengers, it is said, will be held indefinitely on the boat at quarantine, the detention islands, Swinburne and Hoffman, being too crowded to receive them. The *Noordam* had arrived with a case of typhus fever on board, and the *Roma*, which brought a case of smallpox. The War Department, upon request of the Health Officer of the Port of New York, has designated the obsolete transport *Lancaster* for use as a quarantine boat while the present rush of immigrants continues, but the vessel will not be ready for several days.

Charitable Bequests.—Among the bequests provided for in the will of the late Jacob H. Schiff are the following: The Baby's Hospital, $5,000; the Solomon and Betty Loeb Memorial Home for Convalescents, $25,000; the New York Association for the Blind, $10,000; the Tuberculosis Preventorium for Children at Farmingdale, N. J., $5,000; the Montefiore Home and Hospital for Chronic Dis-

eases, $300,000; the Nurses' Settlement, $50,000, and the Federation for the support of Jewish Philanthropic work, $500,000.

"Silencer" for New York City.—Dr. Royal S. Copeland, Health Commissioner, after a preliminary survey of the city with regard to noises, is convinced that a "silencer" is needed to mollify the din. Where noise interferes with sleep it tends to affect the health of the community, and so the Commissioner proposes to stop or reduce to a minimum the multitudinous unnecessary noises. Among other discoveries Dr. Copeland found a pretty general disregard of no-noise signs on hospital streets.

Woman Posing as Graduate Nurse.—The Methodist Episcopal Hospital of Brooklyn has issued a warning to hospital superintendents everywhere to the effect that a young woman posing as Miss Mary Ault, a graduate of that institution, is attempting to secure a position under that guise. The real Miss Mary Ault is practising in Lebanon, Pa., it is stated. It is suggested that superintendents insist upon seeing the diploma of any applicant under this name.

Registration of Disabled Soldiers and Sailors for Rehabilitation.—The Federal Board for Vocational Training has inaugurated a three-months campaign to register disabled soldiers and sailors for vocational education and training. The board announces its determination to see that every ex-service man who is entitled to such training actually receives it. Representatives of the Federal Board in New York City will meet veterans at the following places: Second Field Artillery Armory, One Hundred and Sixty-eighth street and Franklin avenue, the Bronx, Monday, Oct. 18, to Saturday, Oct. 23, inclusive; Eighth Coast Defense Command Armory, Kingsbridge Road and Jerome avenue, the Bronx, Thursday, Nov. 25, to Tuesday, Nov. 30, and Twenty-second Engineers' Armory, Fort Washington avenue and One Hundred and Sixty-eighth street, Wednesday, Nov. 1, to Monday, Nov. 6.

School Health Day.—Dr. Royal S. Copeland, Health Commissioner of New York City, has announced that Health Day will be observed in the schools of the city on November 9. On that day every public school child is to be examined.

Obituary Notes.—Dr. WILLETT S. CONNORS, of Boston, Mass., formerly a practising physician of Brooklyn, N. Y., died October 11, at the age of fifty-one. He was graduated from Dartmouth Medical School in 1891.

Dr. DUNCAN MACDOUGALL, of Haverhill, Mass., died October 15, at the age of fifty-four. He was graduated from Boston University School of Medicine in 1893, specializing in surgery. He was a fellow of the American Medical Association and a member of state and local societies. Dr. MacDougall created considerable comment by his experiments in "the weighing of the soul." By means of delicate weighing devices he weighed bodies just before and immediately after death, and from these observations calculated the weight of the soul at between six and eight ounces.

Dr. RICHARD SCHLEMM of Union Hill, N. J., died Oct. 3, at the age of fifty-five. He was graduated from Bellevue Hospital Medical College in 1885.

Correspondence.

OUR LONDON LETTER

(From Our Own Correspondent.)

LONDON, September 24, 1920.

Conference of the Sanitary Inspectors' Association.—The conference of the British Sanitary Inspectors' Association was held at Margate during the week ending September 18, last. Sir James Crichton-Browne, the well known London mental specialist, gave the presidential address. Referring to the housing problem, he said that after the necessary houses had been built, people must be taught how to live in them. During the industrial period in England the working classes had to a large extent, owing to the nature of their occupations, lost touch of those domestic arts on which the comfort, happiness, refinement and healthfulness of life so much depended, and in these arts they must be now reinstated. Our schools must bestow much more attention on them than they had hitherto done, even at the sacrifice of a little etymology and syntax. Our health visitors must give practical demonstrations in them, and above all our women must be given time to become expert in them. Factory hands and out-workers must be allowed time to become wives and mothers in the full sense of the terms. He saw that 252 bishops assembled in conference at Lambeth decided the other day in favor of the equality of the sexes, which was an anatomical and physiological heresy of the first magnitude, and decreed the revival of the Order of Deaconesses, who were to be permitted to take services, baptize, and preach, which no doubt women of a certain type would with unction do. It was with extreme timidity that he questioned episcopal infallibility, but he ventured to think that the working women of Burnley had shown more wisdom than the bishops in coming to the conclusion, as they had done at the very time of the Lambeth Conference, that there were sexual differences, and that they must leave the mills to the men and stay at home to look after the babies. "For men must work and women must sweep" might be their motto, but perhaps the men might help in the sweeping too.

Dealing with tuberculosis, the president pointed out that after January 1, the insurance committees would have no further responsibility for the sanatorium treatment of insured persons. There seemed to be uncertainty as to where the payments for the treatment of the insured were to come from. It was of the utmost importance that this should be settled without delay, as the demand for treatment was likely to increase largely. One of the evil legacies bequeathed by the war had been an increase of tuberculosis. In England, which seemed to have suffered far less than any other country, the tuberculosis death rate rose from 104 per 100,000 living in 1914 to 137.6 in 1918. It might be anticipated that with a return to more normal political, economic and social conditions there would be a diminished loss of life from tuberculosis. But it might be long before we returned to pre-war conditions. Adverse influences were at work. We had with us great numbers of war-broken and war-worn men, many of

whom had suffered from wounds of the chest or gassing, and who were exceedingly liable to succumb to tubercular disease. It was estimated that there were at present in London 90,000 suffering from tuberculosis. In resisting the attacks of tuberculosis it was practical sanitation in all its branches that was to be depended on. Above all, it was by improved housing that we could reduce the ravages of tuberculosis. Sanatorium treatment was, at present, as it were, under a cloud. He admitted that it had not fulfilled expectations, but these expectations were much too sanguine. It was foolishly boomed by some of its promoters as an almost certain cure, and so there had been widespread disappointment. But our sanatoriums had not, as yet, had fair play. Patients had not been sent to them soon enough, and had not had suitable after-treatment when they had left them. It was now found that at least six months' residence in a sanatorium was necessary to consolidate a cure, even in favorable cases, and it was to be hoped therefore, that hereafter longer duration of treatment would be secured whenever recommended, care being taken that in the case of married men they were given that peace of mind without which treatment could not be fully efficacious, by a liberal allowance to their wives and children while they were away from home. A prolonged convalescence under medical supervision and guidance, and a nicely graduated return to work in a wholesome environment, were necessary if the damaged lung was to be made sound and resistant, and hence the value of industrial and training colonies in which light but remunerative employment, in the open air wherever possible and under medical regulation could be given to patients leaving sanatoriums. Such colonies could not be self-supporting. They must be subsidized from public funds; but considering the excellent results they were already yielding it would be a misfortune if they were not included in our national anti-tuberculosis armament. It would be deplorable if faith in sanatorium treatment should be lost. It was possible that they would yet be able to vaccinate against tuberculosis as successfully as they did against smallpox. Sir James Crichton-Browne's remarks concerning sanatorium treatment were apropos. It is perfectly true that sanatorium treatment in itself and by itself is not regarded with the favorable eyes it was a few years ago. It is also true that, to some extent, the swing of the pendulum is due to the exaggerated statements made as to the wonderful, almost magical effects of sanatorium treatment. This form of treatment has been weighed in the balance and found wanting, that is it certainly will not cure tuberculosis after it has reached a certain stage. But will any treatment cure the disease after it has obtained a hold on the system, and is it not likely always to recur under trying conditions when this is the case? Tuberculosis in the incipient stage can be cured but it is so difficult to meet with cases of this kind and when met with it is quite as difficult to persuade the sufferers, especially if they are working men, to undergo proper treatment. When the disease has become established, the sanatorium has its place in treatment, and industrial settlements and clinics are essential supplements, but it is probably the fact that when once an individual has passed a certain stage in the course of the disease he or she is never fit for the rough and tumble of life again. Both for their own sakes and even more for the good of the community at large, they should lead a life apart, in industrial settlements or colonies and under medical supervision. Among other matters in connection with public health discussed at the Conference was the question of the smoke nuisance. Mr. E. W. Hill of Birmingham, moved that more vigorous action was necessary, from both domestic and industrial points of view, to abate the smoke nuisance, and that the Ministry of Health should introduce stringent legislation to this end. Mr. F. Gentry of Fulham, in seconding the resolution, said only smoke-consuming stoves should be manufactured. It meant scrapping a lot of plants but that was a small matter when they remembered that 25 per cent. of sunshine was now cut off from our cities and towns by smoke. The milk supply was deteriorated in quality when cows grazed in smoke areas, and the only remedy was to remove the cows. The resolution was adopted.

The Future of Hospitals.—The future policy of voluntary hospitals was discussed in Manchester on September 17, last, at a conference arranged and presided over by Sir Arthur Stanley, president of the British Hospitals Association. Sir Napier Burnett said that if hospitals were municipalized they would cost at a very moderate estimate one-third more than at present. He made suggestions for obtaining a large regular income, remarking that the people were willing to give, and it was for the hospitals to set up the machinery. He considered that a state subsidy ought to be limited to a provision of accomodation for patients or staff grants toward new buildings, or money loans to hospitals at a low rate of interest. It was decided to form a regional committee of the British Hospitals Association representing hospitals in the Northwest of England, which will consider a scheme for placing hospitals on a more satisfactory financial basis.

To Fight Typhus.—Mr. Balfour, on behalf of the League of Nations, has addressed a letter to all the governments of the British Empire asking their co-operation in raising £2,000,000 to fight typhus fever. The menace of the disease spreading from Eastern Europe, over the continent of Europe and to the shores of Great Britain, is said to be grave and imminent. Mr. Balfour has issued an appeal to the various governments for the immediate provision of £250,000. In the course of this appeal Mr. Balfour said, "In Russia the disease seems to be epidemic. A medical authority says that it has been swept from end to end by typhus; that scarcely a town or village has escaped; and that half the doctors engaged in combating the pest have died. His statement is confirmed by other witnesses. From the vast center of infection the disease is carried westward by an increasing stream of immigrants. Prisoners returning to their homes, refugees flying for safety, crowd the railways. Two millions of these unfortunate persons have passed the Polish disinfection stations since the armistice

and doubtless many more have entered Poland without being subjected to medical examination. They are pouring into a country already overcrowded where every circumstance, material and moral, combines to favor the spread of infection. So much for the present facts. What forecast can be made about the future? Every competent authority is at one in thinking that the evil is on the increase. Typhus is a disease which normally shows itself more in winter than in summer. If, therefore, conditions were constant, the number of cases at this time of the year should be very small. As a matter of fact, they are not; and it is safe to conclude that, unless effective steps are immediately taken, the plague will be far more deadly in the winter of 1920-21 than it was in the winter of 1919-20." As the *Lancet* points out, no actual work in the direction of staying or limiting the spread of the epidemic can be undertaken until money guarantees have been obtained from the different nations of the league, which so far have not materialized, except in the case of a few countries, including Great Britain and Canada. The same article draws attention to the fact that since little can be done at the present time in Russia, where are the originating foci of the epidemic, owing to political conditions, there only remains the feasible and practical policy of effective epidemic prevention by international action in the border states, especially Poland, Lithuania and Galicia. However, before any steps can be taken, a very substantial sum of money is required, but this sum ought to be forthcoming with the greatest promptitude for humanity's sake and for the sake of self-interest also. To allow the disease to rage unchecked throughout Europe would mean a fearful loss of life and economic disaster.

Obituary.—Lieut. General Sir William Babtie died suddenly on September 15 last while on a holiday at Knocke in Belgium. As a major, R. A. M. C., he won the supreme award of the British army for valor at the battle of Colenso during the South African War. The *Gazette*, in which the announcement was made, said: "The wounded of the Fourteenth and Sixty-sixth Batteries, Royal Field Artillery, were lying in an advanced donga close in the rear of the guns, without any medical officer to attend to them, and when a message was sent asking for assistance, Major W. Babtie rode up under heavy rifle fire, his pony being hit three times. When he arrived at the donga, where the wounded were lying in sheltered corners, he attended to them all, going from place to place exposed to the heavy rifle fire which greeted any one who showed himself. Later on in the day Major Babtie went out with Captain Congreve to bring in Lieutenant Roberts, Earl Roberts' son, who was lying mortally wounded on the veldt, after a gallant attempt to save the guns. This also was under heavy fire." Sir William Babtie, who was sixty-one years of age, was the eldest son of the late ex-Provost Babtie of Dumbarton, Scotland. Having taken his degree in medicine, he entered the army medical service in 1881. In Crete in 1897-8 he was senior medical officer and for his services during the troubles there was given the C. M. G. During the South African War he acted as medical staff officer, being present at the actions leading up to the relief of Ladysmith, and the subsequent operations in Natal and the Eastern Transvaal, his services being recognized by mention in despatches and his promotion to lieutenant-colonel. He became Surgeon-General in 1912, honorary surgeon to the King two years later, and in 1914 went to India as Director of Medical Services. Three months after his arrival the Great War broke out, and he had to provide not only for the Mesopotamia expedition, but for three other overseas expeditions, Egypt, the Dardanelles and East Africa. Sir William was later appointed Director and then Inspector of Medical Services at the War Office, with the temporary rank of lieutenant-general.

The late H. J. Andrews, of the Indian Medical Service, who had been awarded the V. C. for distinguished bravery in India, was the son of Salvationist parents, and although only forty-eight when he was killed in the act of attending to the wounded, he had been himself an officer of the Salvation Army for over thirty years in India. Commissioner B. Cowers, who was in charge of the Salvation Army's work in India, writes that to Dr. Andrews the Salvation Army owes the commencement of its medical work there. He began its work at Nagercoil with a penknife and a razor for surgical instruments, and his first operations were performed in a bathroom. From that beginning he brought into existence a creditable hospital, which he handed over to Dr. Percy Turner, another Salvation Army officer. From Nagercoil he went to Anand in Guzerat. Up to this time he was without recognized medical qualifications, and he and his leaders thought he ought to qualify. He took his medical course, passed with honors, and returned to India to bring into existence another medical center at Moradabad. For all these buildings he was his own architect and overseer of construction. The Moradabad hospital was used for three years for war purposes, and the military authorities took it in many ways as a model.

On September 2, last Dr. Frederick Rutherford Harris died at Eastbourne at the age of sixty-four. Son of a judge in Madras, he studied medicine at Edinburgh University, qualifying M. R. C. S. in 1889 and L. R. C. P. Lond. in the following year. For a time he practiced medicine in Kimberley, South Africa. He then became associated with Cecil Rhodes, who appointed him secretary of the British South Africa Company. South African and later English politics became his chief interest. He was member for Kimberley in the Cape Parliament, and in 1903 was returned to the House of Commons as member for Dulwich.

1. Orchitis in Mumps.—Conrad Wesselhoeft collected, from all the sources at his command, in which the percentage of orchitis is given, 8,153 cases of mumps,

with 1,468 cases of testicular involvement, giving a total incidence of 18 per cent.

4. Transfusion in Obstetrics.—R. S. Titus holds that the ideal of obstetrics is not reached until all has been done that can be done to safeguard the patient against any and all disasters. The accidental bleeding cases, however, are the ones which by no examination can one anticipate. For all loss of blood there is nothing like replacing blood, and severe shock is best treated by blood transfusion. It has been the writer's custom for some time to match the blood of each patient with the blood of the husband and with the blood of a group four person. This is done within six or eight weeks of expected delivery. Strangely enough, in only one case was the husband's blood compatible; on the other hand, the group four person has been compatible with the pregnant patient's blood in every instance. This routine, of course, is not practicable in clinics taking care of patients at home. So far as hospital practice goes, all patients who have had any hemorrhages and cases in which the possibility of hemorrhage is present, should be matched in order to meet the emergency should it arise.

3. Syphilis as a Cause of Delayed Healing in the Non-infected Abdominal Incision.—William Edgar Darnall, in an experience which covers an active service of nearly twenty years, could find but three cases of delayed healing in non-infected abdominal incisions, among hundreds of such cases. This comparative infrequency accords with the experience of most of those discussing the question. No surgeon seems to have had many cases, and yet all can point to a few. His own cases are not enough for definite conclusions, but two were undoubtedly syphilitic and the other was probably so. This evidence is enough to suggest syphilis as one of the causes of delayed healing in the abdominal incision.

7. Results in the Treatment of Neurosyphilis.—Philip Goldfader bases this contribution on a review of the results of treatment of neurosyphilis as conducted by the urological service of the Brooklyn Hospital during 1918 and 1919. In order to treat neurosyphilis successfully the treatment must be instituted as early as possible. Since the spinal fluid is involved in from sixty to seventy-five per cent. of cases during the secondary stage and in twelve to twenty-five per cent. of the cases the pathological changes of the fluid persist, one should be on the watch for early involvement of the central nervous system. During the two years covered by this report diagnostic lumbar puncture was performed in sixty-one cases, which included syphilitic patients who had symptoms referable to the nervous system and those who were ready to be discharged. Out of that number eleven, or eighteen per cent., gave positive fluid findings showing involvement of the central nervous system. During the same period 210 intraspinal treatments were given to forty-two patients. The number of treatments given to any one patient varied between one and thirty. The forty-two patients were divided clinically as follows: Twenty-nine cases of tabes, or 68 per cent.; twelve cases of cerebrospinal syphilis, or 29 per cent.; one case of paresis, or 3 per cent. The diagnosis in each case was determined by history, physical examination, blood Wassermann, and spinal fluid examination. In a few cases no improvement was noted either clinically or serologically; brilliant results were obtained in a few cases, and definite results in a considerable number. It is therefore felt that the results are better with the combined method of treatment than with the intravenous method alone. The tabulated results are as follows: Improved, 27, or 64 per cent.; unimproved, 14, or 33 per cent.; died, 1, or 3 per cent. The writer believes that when properly performed intraspinal treatment is indicated as a routine in all cases of syphilis where clinical symptoms and examination of the spinal fluid indicate involvement of the central nervous system.

1. Clinical Observations on the Digitalis-Like Action of Squill.—White, Balboni, and Viko, in the observations detailed in this contribution, employed the five assay tinctures of squill, all obtained from good pharmacists, and all tested in the Department of Pharmacology of Harvard Medical School. The effect of squill on thirteen cardiac patients with auricular fibrillation and on one with auricular flutter was studied. Their findings are summarized as follows: 1. The digitalis-like action of squill has been studied in fourteen cases of heart disease, complicated by auricular fibrillation in thirteen cases and by auricular flutter in one case. 2. The two definite clinical signs of digitalis action are the production of heart block and the lowering of the *T* wave of the electrocardiogram. 3. Heart block was produced in this series by the standardized tincture of squill only in large dosage. 4. The *T* wave of the electrocardiogram was flattened or inverted by large doses of the squill, similarly as by digitalis. 5. No diuresis occurred even with very large doses of the standardized tincture of squill, except in two cases of edema after the pulse rate had been reduced and the circulation improved. 6. Toxic symptoms were very rare, even with the largest doses. 7. With the reduction in pulse rate (and diuresis) there was subjective improvement in some of the cases. 8. Finally, the conclusion is justified that squill does have a definite digitalis-like action, but only in larger dose than that now stated as an average. e.g. from 2 to 4 drams (8 to 16 c.c.), instead of 15 minims (1 c.c.) of the tincture at each dose.

2. Infectious Eczematoid Dermatitis.—Richard L. Sutton expresses the belief that while the conception of infectious eczematoid dermatitis—a term which is lacking in grace and euphony, as well as in accuracy, but he knows no appellation that will adequately take its place—as first described has undergone some changes, these changes tend to increase rather than diminish the clinical importance of the disorder. While infectious eczematoid dermatitis is in no sense of the term a purely anaphylactic manifestation, in many instances there is a concurrent eruptive phenomenon which can be ascribed to no source other than that of allergy. The association of the two conditions is too frequent to be due to accident alone. In a series of seventy-four case histories, selected at random and scattered over a period of two years, he found a record of concurrent urticarial eruptions in nineteen instances (more than 25 per cent.). The antecedent disorders varied greatly, but were fairly characteristic: lacerated, infected wound of the hand; furuncle of the right thigh; scabies; infected ingrowing toe nail; ecthyma; infected wound of the right forefinger; otitis media; infected, incised wound of the right hand; infectious discharge from the nose; infected wound of the right shin; furuncle of the left axilla; paronychia; infected wound of the thumb, and furuncle

of the scalp. As a rule the anaphylactic manifestations did not appear until after the staphylococcic disorder was well under way. A considerable percentage of these patients had never before suffered from urticaria. In a few instances the wheals were accompanied by vesiculation, with subsequent infection and pustulation. As a rule, the pustules did not heal promptly. The problem of successful treatment is often a vexatious one. Sutton has found, in the earlier stages of the disease, that a mild astringent, such as an aqueous solution of aluminum acetate (0.5 per cent.), or even lead and opium lotion, is more effective than one of the greasy preparations. At the end of forty-eight or seventy-two hours, however, one may profitably begin the use of a weak ammoniated mercury ointment (2 per cent.), together with a bland dusting powder containing a small amount of boric acid. After the tendency to suppuration has been overcome, phenolated zinc oil may be substituted for the mercurial ointment. For the relief of the pruritis which often accompanies the urticarial lesions, calamine lotion, to which liquor carbonis detergens (from 2 to 10 per cent.) has been added, affords much relief. If necessary a small amount of phenol (1 per cent.) or menthol (0.5 per cent.) may be added to the ammoniated mercurial preparation, and the ointment used in conjunction with the lotion. It may be necessary to supplement the local treatment with internal medication and vaccine therapy.

9. Importance of the Vital Capacity in Thoracic Surgery.—Evarts A. Graham. See MEDICAL RECORD, June 5, p. 975.

10. Relative Value of Various Operative Procedures Employed in Acute Empyema.—Carl Eggers. See MEDICAL RECORD, June 5, p. 975.

3. Rupture of Cesarean Section Scar in Subsequent Pregnancy or Labor. Eardley Holland.
4. Public Health in Soviet Russia. (*To be concluded.*) L. Haden Guest.
5. The University Problem. Sir Edward Sharpey.

2. Diurnal Variations in the Hemoglobin Content of the Blood.—Dreyer and his associates describe the method employed and record observations carried out on goats and men. They found that the diurnal variations in hemoglobin percentage met with in man and animals are very cosiderable and may even reach as much as 30 per cent., while 10 per cent. changes are of more or less common occurrence. On an average the excursions seem to be more marked in individuals or animals with a low hemoglobin content of the blood. In attempting to establish the normal hemoglobin content in a series of individuals it is essential to take the observations at a time of the day when the daily variations are found to be of the smallest, *i.e.* late afternoon between 5 and 7 P. M. In the study of the phenomena where alterations in the concentration of blood are concerned it is necessary to view them in the light of the marked normal diurnal variations that may occur.

3. Rupture of Cesarean Section Scar in Subsequent Pregnancy or Labor.—Eardley Holland discusses this subject under the following heads: (1) An account of five new cases. (2) A general discussion on the etiology and anatomy of ruptured scars and an analysis of the literature. (3) The results of a follow-up inquiry into the subsequent obstetric history of a large number of cesarean section patients operated on between 1912 and 1918. From this study he draws the following conclusions: 1. The frequency of rupture of the cesarean section scar in subsequent pregnancy or labor (abortions excluded) is 4 per cent. 2. The cause of ruptured scar is imperfect healing, leading to a thin scar in which muscular union has failed, and which consists of little more than peritoneum and decidua with a varying amount of intervening fibrous tissue. 3. All thin scars stretch during pregnancy; rupture of a thin scar may be determined solely by the intrauterine tension of normal pregnancy or by the uterine contractions of normal labor; or it may be favored by various accidental factors, of which the chief is insertion of the placenta over the scar, with partial separation of the placenta and retroplacental hemorrhage. 4. Other accidental factors are overdistension of the uterus, prolonged or obstructed labor, operative interference, such as internal version, the insertion of hydrostatic bags, and the administration of such drugs as pituitrin. 5. In the reported cases rupture occurred almost as often during pregnancy as during labor (in proportion of three to four), and many cases have been reported as early as the seventh month of pregnancy. 6. The chief cause of imperfect healing is infection of the uterine wound; other causes are imperfect methods of suture and the employment of unsuitable suture material. 7. As regards the suture material, catgut should not be used, for the liability to rupture after catgut is two and a half times the liability after silk. For theoretical reasons silkworm gut is the most suitable material. 8. As regards the incision, the scar of the transverse fundal incision is especially liable to rupture. Only one case has so far been reported of rupture of the scar of the cervical incision.

4. A Summary of the Results of the Serum Treatment of 267 Cases of Cerebrospinal Fever.—T. G. M. Hine realizes that the series of cases collected is far too small to give really reliable statistical figures; nevertheless much may be surmised from a careful analysis of the material available. Of the 267 cases, all treated with the monotypical serum, 18 died of some other disease following on the cerebrospinal fever; indeed, several of the cases were said to have been cured of the cerebrospinal fever before contracting the fatal one. Of the remaining 249 cases all were diagnosed bacteriologically. In these cases the mortality was 31.72 per cent. Of the 249 cases it was found that in 48 the type of invading coccus was never clearly determined, or that it was found too late to be of any value in treatment. As this report is concerned only with cases which received the appropriate serum, these 48 cases are discarded, which leaves 201 cases, with 57 deaths—a mortality of 28.36 per cent. These 201 cases are divided into two groups: (a) cases in which treatment started before the sixth day and was given in adequate amount; (b) those in which serum was first given after the sixth day or insufficiently, and cases moribund when first seen. The first group contains 141 cases with 27 deaths, or a mortality of 19.14 per cent.; the second group has 60 cases with 30 deaths, or a mortality of 50 per cent. From these figures he concludes that the serum must be administered reasonably promptly to be of value. It is of the utmost importance for the proper treatment to ascertain the type of the coccus at the earliest moment possible, as therein lies the only chance of applying curative serum scientifically. It is important to give the serum in adequate quantities and to resolutely stick to the treatment. This, however, is very difficult to prove by figures. It was laid down as a direction early in the epidemic that serum should be given not only as early as possible, but repeatedly daily for at least four days after treatment had commenced, whether the patient was better or not.

5. The Meningococcus "Carrier" Question.—C. W. Ponder confines himself in this report to one clean-cut section of the population tested. At Cambridge in

1916 two cases of cerebrospinal fever had been notified, both in the month of March. In October, seven months after the last case, he swabbed the nasopharynx of most of the staff and employees at the Cambridge Scientific Instrument Company's works outside the town. It should be noted that these employees were earning good salaries and wages and therefore lived in comfortable homes; that none of them had come in contact, to his knowledge, with a case of cerebrospinal fever; that for seven months in a town of about 40,000 population there had been no cerebrospinal fever; and that most of the employees had lived and worked there for many months. This could therefore be described as a "noncontact" population so far as could be found. The following results were obtained: Of the 100 employees swabbed, 41 yielded colonies on Kutscher's medium indistinguishable from meningococcus; in 28 plates such organisms were present either in almost pure cultures or in large proportions. From these plates, 38 of the meningococcus-like organisms gave sugar reactions of meningococcus and good agglutination (generally with serum 1 in 400 or 1 in 800) with one of the monovalent antimeningococcal serums employed. Thus, 38 per cent. of the employees, by cultural and agglutination tests would have been classified as meningococcus carriers if a case had occurred in the works. Further, absorption tests, following as closely as possible the technique recommended by Gordon, were carried out on 19 strains of the above 38 agglutinating strains; of these, 9 absorbed the agglutinin as well as the homologous coccus, and 4 absorbed it partially. Presumably, therefore, 26 per cent. of these employees who had not been in contact with cerebrospinal fever were harboring organisms in their throat which were indistinguishable by every test known from the true meningococcus.

2. The Operative Cure of Pruritus Ani and Vulvæ.—Carroll W. Allen describes an operation for this condition which has in view the separation of the skin from the underlying tissue, thus dividing all nerves which reach the affected parts, rendering them anesthetic, and preventing the skin from immediately healing to the underlying tissues by packing, which is kept up until a firm bed of granulation has formed. This usually requires about one week, when the packing is discontinued and the skin allowed to fall back in place, where it is soon again firmly united, leaving an anesthetic area which nearly equals the extent of the undermined area. In the anal region a series of incisions are made, beginning at the anal margin and continuing outward to about one-half inch beyond the affected area, which rarely exceeds two inches. The incisions are made about one inch apart at their peripheral extremities until the entire perineal region has been covered. The operation upon the vaginal outlet is performed in the same general way. After dissecting up the skin flaps the space beneath is packed with iodoform gauze. After the packing is removed the parts quickly unite. The total disability is about two weeks.

5. The Occurrence of Gallstones in Young Individuals.—Friedenwald and Ullman, since 1896, have met with five cases of cholelithiasis occurring in adolescents, three of whom came to operation, the diagnosis in the other cases being made from the passing of gallstones. Brief histories of these cases are given. From their observations, together with those of other writers, the following conclusions are formulated: 1. Gallstones are rarely observed before the twentieth year, though youth affords no absolute immunity. In the five cases the ages varied between fifteen and eighteen years. 2. As in older individuals, in the young the condition is found more commonly in females than males. In this group there were four females to one male. 3. The clinical picture in the young is quite similar to that observed in adults. Pain and tenderness under the right costal arch are constant symptoms and were present in all the cases. Jaundice is common and was present in three cases. 4. In none of the cases was there evidence of any fecal or general infection which could be considered as a causal factor.

4. What Are We Doing for the Mentally Backward Child?—Charles E. Boynton, under the head of treatment in general, makes the following suggestions: 1. Never make a diagnosis of idiocy unless the size of the head rules out all possibility of any hope of improvement. 2. Have a Wassermann made to rule out syphilis or treat it, if found, and have the eyes examined by a competent oculist to exclude amaurotic family idiocy. 3. Examine the child thoroughly, and especially for evidence of insufficiency of the endocrine organs. 4. Examine the urine, stools and blood for evidence of any toxic conditions. 5. See that the child is well nourished and that proper food is supplied. 6. Employ tonics and general hygienic measures, not forgetting to give plenty of water. 7. Try in every way possible to attract the attention and teach the child to concentrate the gaze; feel of the hands and educate the grip, the muscles and special senses. 8. Endeavor to secure the mother as an ally. Encourage and train her as much as possible without promising her anything. If she is intelligent and will cooperate, she makes the best possible trainer up to the time the teacher or the psychologist is ready to take charge.

Il Policlinico.

June 7-14, 1920, xxvii, 23-4.

Medical Treatment of Dysenteric Hepatic Abscess.—Pontana sums up his serial article on this subject as follows: The work of the clinic and laboratory shows that in masked dysentery the *Ameba histolytica* is recognizable in the feces and in the "pus" in positive puncture of the liver, but a negative result does not exclude hepatic "abscess." The punctate is not really pus, but an albuminous fluid containing cellular detritus, a few degenerated cells, red blood corpuscles, fatty droplets and fat crystals. This find is so characteristic that even in the absence of anything specific the author regards it as diagnostic of hepatic abscess. The fact that this fluid is not true pus may explain why a medical cure is attainable. Emetine chloralhydrate injected intramuscularly in proper dosage will arrest suddenly the necrotic process and cause the absorption of the socalled abscess. If microorganisms can be cultivated from the "pus" emetine proves equally curative. for in this situation such organisms are to be regarded as saprophytic and they are rapidly destroyed. If the organisms are truly pyogenic and can transform the fluid into true pus no medical treatment will avail and surgical intervention is imperative. Neither the severity of the disease nor the size of the "abscess" are contraindications to medical treatment. The coincident dysentery must, of course, be treated. If multiple "abscesses" form they may be beyond the reach of sur-

gery if the latter is indicated. Generally speaking, the amebic abscess must pass back from the domain of surgery to that of medicine.

La Presse Médicale.

July 31, 1920, xxviii, 53.

Quinine in Fibrillation and Tachysystolia.—According to Schrumpf of Lausanne, quinine seems to exert a curative action on fibrillation and auricular tachysystolia occurring in paroxysms. He however is not yet convinced of the truth of this claim. It is certain that once these conditions become fully established, quinine cannot modify them. Quinine appears to transform fibrillation into tachysystole and to regulate the action of the ventricle. In these two conditions quinine improves the circulation and regularizes the pulse, but not by suppressing either the fibrillation or the tachysystolia. Regulation of the ventricular action may be brought about either as a result of auriculoventricular block or through the development of a regular tachysystole. Quinine is best given with digitalis of high dosage, and preferably in prefibrillation cases and early cases of fibrillation; here their synergism appears to be perfect.

Intramuscular Injections of Ether in Pertussis.—Cheinisse gives a synthetic review of the labors in this field of Weill, Dufourt, Audrain and Castel, Renard, Deherripon, Dalche, Variot, Courcoux, and others. The consensus of favorable reports and opinions makes it almost certain that this resource surpasses anything heretofore tested for this malady. There are some differences of opinion, as when Dufourt asserts that the treatment is valueless after bronchopneumonia has complicated the pertussis, while Deherripon finds it completely suited to the complication of these conditions because the ether serves as a cardiac stimulant. As a coincidence a recent writer on bronchopneumonia in infants (Lasalle of Thonon), without reference to the cause in the individual case, recommends ether injections for the disease.

La Presse Médicale.

August 11, 1920, xxviii, 56.

Inflamed Axillary Lymphnodes in Nonulcerated Breast Cancer.—Bonneau describes a case of this type in a woman of fifty-seven who had never borne nor nursed a child. There had been a small lump in the breast since the age of eighteen and seven years before her visit she was advised to have it removed. She did not take this advice and four years later noted discomfort on moving the arm, swollen arm veins and pain. She still refused operation until the nipple showed retraction, when she consented. The tumor was the size of an orange, the skin above was adherent, but there were neither deep adhesions nor axillary lymphnode enlargement. Halsted's operation was performed and a neoplastic focus was seen in the extirpated mass, but there were none of the usual evidences of malignancy. There was no tumor capsule, and no deep adhesions and the muscles, skin and nipples were intact. There were a number of small axillary lymphnodes, not cancerous. The microscope showed an epithelioma of low proliferative activity; infiltration of the cancerous type could be seen and there were central and peripheral sclerotic processes. With few exceptions all the changes in the lymphatic system represented a reaction of inflammatory type. This growth is not of the type of the ordinary closed breast cancer because of its low malignancy. Noncancerous enlarged lymphnodes are not uncommon in closed cancer of the breast, and in 1909 Fague wrote a thesis on this subject. Another point of interest lay in the fact that the woman was fat, which usually makes against a favorable prognosis. In cases like the present to clear out the axilla and take the other steps incident to a radical operation is meddlesome and leads to great disability. The only resource in theory is to open the axilla and excise a portion *en bloc*, then making sections with the freezing microtome. If the lymphatics are found to be noncancerous, Bonneau says, the dissection of the axilla may be discontinued and the wound closed.

La Riforma Medica.

July 31, 1920, xxxvi, 31.

Postinfluenzal Immunity.—Falcioni anticipates by the statement that the general belief is in favor of an acquired immunity following the pandemic of 1918. This, however, is limited and may extend over not more than four months, but usually a year or even longer. A society formed for the study of influenza in Milan which met last April came to certain conclusions. The absence of laboratory criteria, the numerous types and varieties of influenza so called, the regular winter and spring visitations, etc., all play a rôle in the discussion of immunity. The fact that the same subject has undergone several successive attacks of "influenza" need not mean that he has no immunity. But another element may help us here. True influenza is highly contagious, passing rapidly through a family and from one to another. In two successive waves of this type it was often noted that the immunes of the second wave had been victims of the first wave; and that those who escaped the first wave often succumbed to the second. The immunes of the second wave were true immunes, for they were frequently exposed in caring for the victims of that wave. This sort of immunity lasted not only from May-June to October, but was also in evidence during 1919. Hence the author's criterion of one year or more of immunity for the majority originally attacked. In a minority of cases, in which victims of the May-June wave escaped the October wave, we can only speak with certainty of about four months' immunity, for a certain number contracted the disease in 1919. This contingent seems to have been very small. The fact that the early victims were protected during 1919 goes to show that influenza in that year was the genuine disease and not one of the milder or false types. The author does not appear to have any belief in the theory of a life-long immunity following an attack of genuine influenza. Yet many who had suffered from an attack of influenza in the epidemic of 1889-90 escaped during the pandemic invasion of 1918-19, and such were generally credited with an immunity conferred by their attack twenty-eight years before.

Revista Española de Medicina y Cirugia.

May, 1920, iii, 23.

An Epidemic of Nephritis.—Roset of Valls states that in 1904, month of April, a quasi epidemic of nephritis appeared in Valls. It followed a cold spell and there was seen at the same time an accumulation in the usual incidence of erysipelas, phlegmons, puerperal infection, anginas and diphtheria. Both sexes and all ages were affected by the morbidity. The exact number of cases of nephritis was 21 in a population of 13,228, or 1.6 per 1,000. Most of the 21 consulted for edema of the face and hands. In no instance did a case of nephritis follow an angina or other focal condition. The urine showed a tendency to hemorrhage and contained a pyogenic streptococcus. A few of the patients developed uremia. In one elderly patient the acute affection became chronic. In one youth of eighteen the affection pursued a fulminating course, uremia supervening at an early date; the patient was given up, but a hot bath was followed by extensive critical diuresis. It is of interest to note that two years after this episode Eichhorst, the well known Swiss clinician, reported two cases of the same type. None of the cases is mentioned as having ended fatally.

Adenoid Vegetations in the Adult.—Suñé Medán of Barcelona analyzes 62 cases of adenoids in the adult, of which number 41 occurred in males. The word adult, however, is misleading, for the author apparently regards the period of childhood as extending only to the age of thirteen, while adolescents are classed as adults. There are twenty cases in the age period twenty-two to forty and six patients were aged thirty and upward. There is no case over forty, although rhinologists state that cases are seen in advanced age. The author elsewhere analyzes his material as follows: there were thirty cases in the "period of puberty" and thirty-two in the "adult" period, which he reckons as from eighteen upward.

Book Reviews.

TREATISE ON GENERAL AND INDUSTRIAL INORGANIC CHEMISTRY. By DR. ETTORE MOLINARI, Professor of Industrial Chemistry at the Royal Milan Polytechnic and at the Luigi Bocconi Commercial University at Milan. Second edition, translated from the fourth revised and amplified Italian edition by THOMAS H. POPE, B.Sc., F.I.C., A.C.G.I. With 328 illustrations in the text and two phototype plates. Philadelphia: P. Blakiston's Sons and Co., 1920.

THE scope of this magnificent work is indicated by the title. It will be seen that the book is not a chemistry for medical students, but even medical schools should have the volume on their library shelves. The practical applications of chemistry to the various arts and industrial processes are handled here in a satisfactory manner. Useful tables of statistics and of the cost of raw material occur frequently. The discussion of the fundamental laws and principles of chemistry occupy the first part of the book, and their presentation from a somewhat novel angle adds to the interest of the topics. There seems to be some variation in the date of the statistics given; in some cases the figures are brought down to 1916, while in many others they are carried only as far as 1911. It is doubtful if the cost of the various materials has remained constant; indeed, it may be questioned if any of the prices quoted are of more than historical value. The volume deserves a much better index than it now possesses; a book of 850 large pages, bristling with information, cannot be satisfactorily indexed in seventeen pages. We have looked in vain for the Carrel-Dakin solution, both in the index and also in the body of the book, but perhaps that item does not come within the scope of the volume.

THE CATARRHAL AND SUPPURATIVE DISEASES OF THE ACCESSORY SINUSES OF THE NOSE. By ROSS HALL SKILLERN, M.D., Professor of Laryngology, Medico-Chirurgical College, Post-Graduate School, University of Pennsylvania; Late Lieutenant-Colonel, M. C. U. S. A.; Fellow of American Laryngological Society; Fellow of the American College of Surgeons; Fellow of the American Laryngological, Rhinological and Otological Society; Fellow of the New York Academy of Medicine, etc. Third Edition. Thoroughly Revised and Enlarged. Philadelphia and London: J. B. Lippincott Company, 1920.

IT is gratifying to learn that this book has survived the turmoil of the war which put an end to much deserving medical literature, and that a new edition has been called for. We do not find much that is new here, nor should we expect to, for in truth there has been but little advance in our management of sinus diseases in the past few years. The author states that, while in service, he was particularly interested in noting the influence of diseased sinuses on the general system, especially on the individual capacity of the recruit and the man in action. What he learned in this respect and also the knowledge gained of war wounds of the sinuses, so far as this applies to civil life, have been incorporated in this new edition.

ARTERIOSCLEROSIS AND HYPERTENSION, with chapters on Blood Pressure. By LOUIS M. WARFIELD, A.B., M.D. (Johns Hopkins), F.A.C.P., Formerly Professor of Clinical Medicine, Marquette University Medical School; Chief Physician to Milwaukee County Hospital; Associate Member Association of American Physicians; Member American Association of Pathologists and Bacteriologists, etc. Third Edition. St. Louis: C. V. Mosby Company, 1920.

AS it is eight years since the publication of the second edition of this work one can appreciate the necessity for many changes in the text to bring the teaching in line with the theories of the present day. A great deal of work has been done in both of these allied fields and a considerable shifting of opinions has taken place. The author, for instance, has discarded the notion of arteriosclerosis as a marked entity with a definite etiology but regards it rather as a simple degenerative process following a number of provocative factors.

The author states somewhat apologetically in the preface that his book embodies his personal views with little borrowing from the literature. He need not apologize, for this is what lends particular value to the book, and if more authors insisted upon their own views and left a review of the literature to writers of encyclopedic treatises, there would be a distinct and most desirable advance in medical teaching. The book is well printed and well illustrated and it is an occasion of satisfaction that it has been deemed worthy of a third edition.

THE X-RAY ATLAS OF THE SYSTEMIC ARTERIES OF THE BODY. By H. C. ORRIN, O.B.E., F.R.C.S., Ed., etc. Price $5. New York: William Wood & Company, 1920.

THIS atlas comprises twenty-one plates of the systemic arteries, the latter having been injected with an opaque substance. The volume therefore counts as an anatomical work which may be regarded as a control of an atlas of dissections of the same vessels. The first three plates are devoted to the fetal arteries after which come the head and neck, upper extremity, thorax, abdomen, pelvis and lower extremity of the adult vessels, concluding with two stereoscopic radiographs of the head and trunk and extremities respectively. Most of the plates are accompanied by a certain amount of illustrative text.

LA EPIDEMIA DE GRIPPE DE 1918-19. Por JOSE W. TOBIAS (Thesis for the Title of Doctor of Medicine, National University of Buenos Aires). Buenos Aires: A. Guidi Buffarmi, 1920.

THIS thesis comprises over 200 pages illustrated by 26 plates. The epidemiology of influenza is first discussed with special reference to the domestic types of the disease. The bacteriology follows, going back to the earliest episodes before Pfeiffer's time. Pathological anatomy is the subject of the third chapter, and the state of all the viscera is considered. The next topic is the interrelationship beginning with the domestic and pandemic influenza. The three remaining chapters are devoted to symptomatology, clinical types, and prophylaxis. There is no separate section on treatment. Many case histories are given with an extensive bibliography.

DIE GESCHLECHTSKÄLTE DER FRAU (Eine Psychopathologie des Weiblichen Liebeslebens). Von Dr. WILHELM STEKEL. Berlin and Vienna: Urban & Schwarzenberg, 1920.

IN a brief review of such a subject we can do little more than give an outline of the plan of the author. His 15 chapters which comprise nearly 400 pages are devoted among other themes to love at first sight, conditions under which love operates on the individual, sexual trauma of adults, psychology of the frigid woman, infantile fixations, the will to "unlust," imagined love, the warfare of the sexes, psychoanalyses of certain patients, etc. The book contains no analytical index. The author, judged by the quotation at the beginning of his book, evidently regards frigidity and lack of attraction towards men as made up of inhibitions and not as elementary defects. Like all works of this type the subject matter is eminently anecdotal, aside from the many detailed case histories. The subjects psychoanalyzed comprised a dyspareunic, a woman compared by the author to Messalina, and a transvestite. The "will to unlust" appears to be a subconscious volition to antagonize sensual pleasure.

X-RAY OBSERVATIONS FOR FOREIGN BODIES AND THEIR LOCALIZATION. By CAPTAIN HAROLD C. GAGE, A.R.C., O.I.P., Consulting Radiographer to the American Red Cross Hospital of Paris. St. Louis: C. V. Mosby Company, 1920.

THIS small volume is dedicated to Béclère, who is the head of the radiological department of the Military Government, Paris, and contains an introduction by Dr. Joseph A. Blake. The number of pages is 83, of illustrations 55. The contents of the volume are wholly technical, which accounts perhaps for its small size. There is no subdivision of the text into chapters or sections. Perhaps the title should have been a "technical manual of localization of foreign bodies, etc." No case histories are incorporated. Although apparently the last word in technique, we note that the book was composed in June, 1917. The Coolidge tube is mentioned only in a footnote as likely to supplant the coil described in the text.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held May 20, 1920.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

THE program of the evening was arranged in cooperation with the Section of Neurology and Psychiatry.

Experimental Studies in Encephalitis Lethargica, with Lantern Slides.—Drs. ISRAEL STRAUSS and LEO LOEWE made this presentation. Dr. Strauss referred to their former communications, in which they had established the fact that epidemic encephalitis was due to a filterable virus and that they had successfully cultivated this virus. The experimental work embodied in these reports demonstrated the close relationship of the virus and the microorganisms to the nasopharynx. Berkefeld filtrates of the nasopharyngeal mucous membrane from fatal cases of epidemic encephalitis and cultures of these filtrates when injected intracranially into monkeys and rabbits, produced the typical clinical and pathological picture of the disease. The present report was a continuation of this experimental work and indicated the value of animal inoculation in the diagnosis of epidemic encephalitis. Monkeys and rabbits that succumbed were examined post mortem, and microscopic slides of sections were exhibited which showed characteristic lesions, consisting of meningitis with round cell infiltration, perivascular and adventitial infiltration with mononuclear cells, focal infiltration with round calls, punctate hemorrhages and edema. Filtrates of nasopharyngeal washings from a number of patients with epidemic encephalitis were cultivated on kidney-ascitic fluid media, with positive findngs in a large percentage of the cases. Subcultures of many of these strains were taken successfully and carried along through several generations. In a number of instances the organism was recovered from the brains of animals injected with the virus of these nasal washings and in several instances from the brains of rabbits injected with organisms isolated from these nasopharyngeal washings. Cerebrospinal fluids from patients having epidemic encephalitis were injected intracranially into rabbits in amounts of 0.25 to 1 c.c., and about 50 per cent. of the rabbits that died showed the characteristic microscopic lesions. Animal inoculation had served to confirm the diagnosis in about 75 per cent. of the cases included in this study. Cerebrospinal fluids had yielded the filterable microorganism in more than one-half the fluids cultivated. Control studies had been uniformly negative. Briefly stated, their conclusions were: (1) That the virus of epidemic encephalitis could be maintained by regular rabbit passage; that it became a fixed virus, killing the animal on the fourth, fifth or sixth day, with symptoms of torpor, myoclonia, meningeal irritation, fleeting epileptiform convulsions, rigidity and typical lesions. After many passages through this species of animal it became pathogenic for catarrhine monkeys. (2) The virus was not cultivable by the usual methods. (3) It could be preserved in glycerol. (4) It was a filterable virus, passing with facility through Chamberland filters one and three. (5) It could be inoculated into the rabbit either by the cerebellar route or by way of the peripheral nerves. Subcutaneous inoculation had no effect.

Dr. SIMON FLEXNER said he thought all present had reason to congratulate Dr. Strauss, Dr. Loewe, and themselves on the presentation that had been made this evening. This subject of encephalitis lethargica had been and still was a very puzzling one; it was also a very serious one. Those who had come directly in contact with the disease realized the last proposition. The question which had been uppermost in the minds of pathologists had been the relation of this new epidemic disease to other epidemic diseases of the central nervous system, and the one with which we had become most familiar was poliomyelitis. As Dr. Strauss had said, when encephalitis lethargica first appeared in England the two diseases were confused. However, studies of encephalitis lethargica, in relation to its characteristic clinical symptoms, its seasonal incidence, and its inoculability into monkeys went to show that the two diseases were distinct. If epidemic encephalitis lethargica was not poliomyelitis the question was what was it. Was it a new disease, or was it an old disease not recognized before? That question was still a subject of contention. There was a form of encephalitis observed during the epidemic of influenza, and the question arose as to whether it was related in some way to influenza or whether it was merely coincident with influenza. If the work which Drs. Strauss and Loewe had presented was confirmed, then these two diseases would be shown to be entirely distinct from each other. Dr. Flexner said he thought the history of the two diseases as they had appeared recently indicated that they were distinct diseases. Encephalitis lethargica was first described in Vienna in 1916 and 1917, and that was before this last epidemic had occurred. There was no epidemic of the disease here in 1916 and 1917; at least none was recognized. There was such an epidemic, however, in western Europe a year later, coincident with the influenza epidemic, and a similar epidemic had occurred in this country coincident with the influenza epidemic. A post-influenzal form of encephalitis had been recognized since 1892, and it was with this disease that encephalitis lethargica had been confused. The speaker's observations in both epidemics led him to find out if in 1892 there was a worldwide epidemic of encephalitis. There were no records of such a worldwide epidemic of encephalitis following the epidemic of influenza in 1892, and considering the state of medical knowledge at that time if there had been such an epidemic coincident with the epidemic of influenza it would have been noted in the literature of that period. Dr. Flexner stated that he was of the opinion, therefore, that this was an independent disease, not related to poliomyelitis or influenza. Encephalitis lethargica was always present in the winter, while poliomyelitis occurred in the summer and fall. Epidemics of diseases of the nervous system were common in history. One had occurred in New South Wales in 1916-1917, in the summer time. Those who studied the disease there thought at first it was poliomyelitis, and then became convinced that it was not poliomyelitis and called it "X" disease. In a certain article by an Australian writer, who discussed encephalitis lethargica as it occurred in Austria, the opinion was expressed that the "X" disease in Australia was the same as the encephalitis lethargica existing in Austria. The speaker, however, thought that was a fallacious opinion, inasmuch as the incidence of the diseases was different, that in Vienna occurring in the winter and that in New South Wales in the summer, and, in addition, the disease in Australia was easily transmitted to monkeys, while transmission was very difficult in the case of encephalitis lethargica. Moreover, they found that the Australian disease could be transmitted from monkeys to sheep, calves, and horses. If that was true they were dealing with a disease quite unlike epidemic encephalitis and poliomyelitis. The important point from the public health standpoint was: Were there three distinct epidemic diseases of the central nervous system moving about the world to-day? Dr. Flexner said that might be. He had had tissues sent him from cases of the "X" disease of Australia and had studied sections carefully and compared them with sections from cases of poliomyelitis and epidemic encephalitis lethargica. It seemed to him that the epidemic in New South Wales might have been an atypical poliomyelitis.

Dr. Flexner said it would not be fair if he did not say a few words about their experimental work with encephalitis lethargica at the Rockefeller Institute. They had made attempts to communicate the disease to animals and it had failed where the gentlemen from Mount Sinai had been successful. He had not succeeded in spite of the fact that he had used the same materials in a large number of animals, some thirty or forty monkeys and over one hundred rabbits. The materials employed were central nervous system tissues, cerebrospinal fluid, washings from the nasopharynx, and the mucous membrane from the naso pharynx of human beings dying of encephalitis lethargica. This work of Drs. Strauss and Loewe was of the utmost importance if it was confirmed, as he believed it would be, since Levaditi had apparently been successful in reproducing the disease in animals. Why the production of the disease experimentally was so easy for some and so diffi-

cult for others was a question only the future could answer. There was one practical point, however, which he thought should be mentioned, and that was with reference to the use of animal inoculation as a diagnostic measure. This attempt had failed so often in their hands that he would hesitate to place any value on it at the present stage of their studies. The lesions shown by the speaker on the screen, however, closely resembled the lesions of encephalitis lethargica seen in human beings. Dr. Flexner then threw a number of slides on the screen, showing that other affections of the central nervous system produced lesions very similar to those attributed to encephalitis lethargica. Among these were two slides from cases of African sleeping sickness, in which the lesions were very similar to those shown in the cases of encephalitis. The lesions in the African sleeping sickness were more pronounced in the cortex, while those in encephalitis lethargica were more pronounced in the basal ganglia. In sleeping sickness there was a more pronounced meningitis than in encephalitis lethargica. The pathological condition in African sleeping sickness was a meningoencephalitis, but the lesions were similar to those of encephalitis lethargica. The same was true of the Australian disease. The similarity of these lesions indicated that lesions of this kind could be produced by a variety of infectious agents.

DR. WILLIAM H. PARK congratulated Drs. Strauss and Loewe upon the thoroughness with which the work had been done and presented, and expressed the hope that the difference in the results between th two laboratories, that at Mt. Sinai and the Rockefeller Institute for Medical Research, would be cleared up. He said he could understand why they might have had such different results with monkeys if different varieties had been used, but he did not see why there should have been the difference in the experimental work on rabbits. Possibly a difference in the filters might explain the difference in their results. Dr. Park asked if they had found enough mixed infections to suggest that secondary infection might play a part in the picture presented. He stated that they had examined at the Department of Health only two brains of subjects dying of encephalitis lethargica and on one of these they had found the streptococcus abundantly present and this had suggested the idea that this complicating organism might have had much to do with the fatal outcome. It would be interesting to know whether complicating organisms occurred frequently enough to suggest that they might have an important influence on the course of the disease.

The Symptomatology of Encephalitis Lethargica.—DR. ISADORE ABRAHAMSON made this contribution in which he discussed somewhat fully two functions the disturbance of what constituted the fundamental physiological discord in this disease. He stated that for convenience it was customary to assume the existence of a typical form of morbid response and to describe it. The typical form, however, was more or less mythical; it did not exist. In different areas of the same epidemic at different times, different group reactions dominated. He therefore deemed it better to consider somewhat fully the fundamental disturbances of the mental and motor functions than merely to enumerate all possible symptoms, signs and syndromes of encephalitis lethargica.

Mental Disturbances in Lethargic Encephalitis.—In discussing this phase of the subject, the essayist said that the toxins of encephalitis acted as a poison to protoplasm. This poison attacked all cells, individually and in mass, and under its influence cell life became torpid. All cells, however, were not equally vulnerable to the toxins of encephalitis lethargica. The main brunt of the attack and its consequences fell upon the nerve cells. Functional correlation which was chiefly nervous, therefore, suffered more than that which was partly under chemical or mechanical control. Thought was a function wholly dependent upon cerebral nerve cells; it was, therefore, a function which must inevitably suffer in this disease; and lethargic encephalitis invariably gave rise to mental disturbance. The superficial form of the disturbance in the same case varied according to the stage of the disease and in different cases according to the severity of the infection. Somnolence and insomnia, mania and depression, delirium and coma, confusion and catatonia might all be observed; these were essentially variations in the severity and phase of the disturbance and not in its nature. Dr. Abrahamson described minutely the somnolent state of the patient, the depth of which had no correspondence with the temperature, respiration, blood pressure, or blood picture, since all of these might remain normal. The somnolence came on gradually and usually disappeared gradually, leaving the patient in a state of utter weariness and inability to find refuge from that weariness in sleep. The somnolence might deepen into stupor from which the patient was not easily aroused to conscious response. This stuporous state resembled very closely a drug intoxication. The patient passed into a state known variously as catalepsy, flexibilitas cerea, narcolepsy, or catatonia, according to its severity. This state might pass away leaving confusion, faulty orientation, and memory loss of the Korsakoff type. It also, as a rule, left a very real depression, in which there might be anorexia, with many other inhibitions, and lack of initiative and perseverance, as well as confusion and extreme poverty of thought. The stupor occasionally deepened into coma, which, as a rule, ended fatally. The coma presented no features distinguishing it from coma in other diseases. The coma might also appear rather suddenly as a terminal phenomenon, and be due not so much to the specific poison of lethargic encephalitis as to acidosis. Dr. Abrahamson reviewed the views of McNulty who had given the mental disturbances of lethargic encephalitis special study and said he felt that he could not compare the mental picture of the consciousness of the victim of lethargic encephalitis with personal experience. What was disclosed of them was usually too fragmentary for analysis. The hallucinations seemed to differ in few respects from those seen in other profound intoxications. The associations and perceptive faculties were not retained and consciousness was clouded, and greatly restricted, so that on command it became exclusively occupied by the response; and volition was practically suspended. The hallucinations, therefore, probably arose unsought, not as exaggerated visual ideas, for all ideas were minimized, but as essential hallucinations, which whether of strong or weak imaginative force were the result of intoxication. Most of these hallucinations were visual. Some of them seemed to be endowed with all the elements of reality; the critique was therefore lacking. The part of the cells chiefly affected by the toxins of lethargic encephalitis was not yet determined. But any poison which reduced the vitality of the cell *ipso facto* lightened the resistance at the synapse. And the persistent sequence of severe intoxications, the psychoses, the Korsakoff phenomena, and even the protracted recovery showed that beside nutritive changes, actual structural disturbances might also occur—a true inflammation of the brain cells with destruction of the cellular processes.

Motor Disturbances in Lethargic Encephalitis.—In discussing this phase of the symptomatology the essayist stated that as had been pointed out the main stress of the toxemia of lethargic encephalitis fell upon the nerve cells. At certain sites the toxic action was reinforced by the direct attack of the Loewe-Strauss bodies upon nerve cells. The nerve sites attacked by these organisms was determined in part by the particular mucous membrane in which the initial invasion took place. From this area the organisms were carried along the lymphatics to the central nervous system. As the habitually invaded area was the nasopharyngeal musoca, the nerve sites usually attacked were in the head end of the nerve axis. But if the intestinal musoca were the invaded area, then the brunt of the attack fell upon the caudal end of the nerve axis. The direction, extent, and severity of the attack upon the nervous system determined the nature and degree of the resulting functional disturbances. Since the nervous mechanism which subserved the function of movements was coextensive with the nervous system, in lethargic encephalitis movements were invariably deranged. Lethargic encephalitis might affect the function of movement in all predictable ways, to all conceivable degrees, and at all possible points of the motor mechanism. In different epidemics, and even during the same epidemic in different localities, or at different periods, particular varieties of motor derangement tended to

prevail. But in spite of such episodal variations, among the qualities of the motor defects of lethargic encephalitis were certain that were banal and certain that at least in their emphasis were distinctive and pathognomonic. Of any two movements that which depended upon the more extensive nerve mechanism was, other things being equal, the more liable to derangement in this infection. Where separate paths conveyed habitually correlated impulses to an associated group of muscles, sudden interference with any one path might disorganize temporarily the whole function. The initial result of the lesion might, therefore be wholly disproportionate to its cause. The widespread nerve supply of the motor mechanism of the eye seldom wholly escaped implication in lethargic encephalitis. The writer described in detail the effect of the disease on the ocular mechanism and on the facial muscles, and said that occasionally the motor root of the fifth nerve suffered and that the tongue was implicated almost as frequently as the face. The soft palate and the constrictors of the pharynx might be so weakened as to render swallowing difficult or impossible, and to necessitate feeding by the stomach tube. Of the cranial nerves the twelfth, the spinal accessory, was least commonly affected. As the cranial nerves were affected, in like manner the disease attacked the spinal motor nerves. Not rarely banal hemiplegias or monoplegias occurred. In these the distal muscles of the extremities were more involved than the proximal. Besides this banal hemiplegia, rigidity and loss of power in lesser degree, often hemiplegic in distribution also occurred. The characteristic tremor in lethargic encephalitis, like the tremor of Parkinson's disease visibly affected the extremities more than the head and trunk, and was exaggerated by emotional excitement and by indirect intention. The lethargic tremor, however, was not present "at rest"; it markedly increased by direct intention and grew in amplitude as the objective of the movement was approached, but was coarser, less symmetrical, and more irregular than the typical Parkinsonian tremor. In addition to the coarser tremor, the small, rapid tremor seen in most acute infectious diseases occurred also in lethargic encephalitis. Occasionally epilepsy developed. The most characteristic of these motor disturbances was instability of posture. The writer described how loss of muscle tone occurred and showed that in lethargic encephalitis the lack of power to preserve posture was not due to a general lowering of muscle tone for it affected only individual muscles or groups in particular areas, but that the nerve mechanism which subserved the sarcoplastic portion might be implicated, giving rise to the peculiar loss of power to maintain posture. Depression of the tone of the sarcoplasmic portion of the agonists was probably the basis of this postural fault, but the tone of the antagonistic muscles might also be unduly exalted. At present the exact seat of the defect was not known. This postural defect might arise when the lower motor neuron was demonstrably intact. It affected postures voluntarily assumed. There must exist, therefore, no one final path to voluntary muscle, as Sherrington taught, but two paths, namely, the lower motor neuron, its cell in the anterior horn and its white medullated fiber passing to the voluntary muscle; and the postural nerve of voluntary muscle. In poliomyeltitis the lower motor neuron was mainly and commonly affected, and the postural nerve as a rule escaped. In lethargic encephalitis the lower motor neuron as a rule escaped and the postural nerve was mainly and commonly affected.

DR. BERNARD SACHS said, in reference to a point touched upon by Dr. Flexner, he remembered very distinctly the epidemic influenza in 1889 and 1892, and recalled very distinctly that following that epidemic there were cases diagnosticated as basilar meningitis which to-day would be designated encephalitis or meningoencephalitis. He was certain, however, that those cases were not at all similar to the cases they had been seeing recently. He was certain, too, that if the cases at that time had been similar to those they were now seeing he would have taken cognizance of it. There was no lethargy. The lethargic condition as observed in the epidemic form was interesting from the clinical point of view. It was not like any other form of coma that was seen. In any other condition in which the patient appeared deeply comatose he could not be aroused, as he could be in this condition, and then fall back into deep coma. What we had encountered during the last year was a new disease entity, or at least one we had not been familiar with before. Dr. Sachs also called attention to the fact that we had known of acute hemorrhagic ecephalitis as an expression of infection. This subject had been discussed in connection with infantile cerebral palsies and it was noted that in connection with acute infections one might find an acute hemorrhagic encephalitis as a basis in a certain number of cases. He did not think the perivascular extravasation and mononuclear infiltration was pathognomonic of this especial epidemic disease. The proof as to the nature of the disease would have to come through new bacteriological and cultural methods. The disease had been very striking in that at no other time had they had the opportunity of having patients come into an office complaining of double vision without any other symptoms, and in such cases they had been able to predict that somnolence would follow. In that way it had been a unique experience. Before this epidemic if a patient came complaining of double vision one thought of cerebral lues or early brain neoplasm. Another impressive experience was the development of what appeared to be acute paralysis agitans. That type of the disorder seemed to be disappearing, but there was a recurrence of it during the past autumn and winter. In encephalitis lethargica one might meet with varying types of disease referable to the pons, medulla, or basal ganglia. Dr. Sachs said the term encephalitis lethargica did not accurately describe the condition, since it was not the encephalitis which was lethargic but the patient; it would be better described as epidemic central or basilar meningitis. Dr. Sachs also referred to another peculiar feature of the disease, namely, a recurrence of the symptoms weeks after the patient was on the road to recovery. There were many difficult questions in connection with the disease, and one of these was the difficulty of differentiating it from tuberculous meningitis. One could not say that as yet we had made any absolutely differential points between these two diseases.

DR. FOSTER KENNEDY called attention to the fact that Dr. Dana stated that in 1889 he saw cases that passed under the name of grippal catalepsy, and it seemed to him that this term might with certain reservations be applied to encephalitis lethargica. Dr. Flexner laid a great deal of emphasis on the laboratory discovery that the disease was not the same disease as poliomyelitis. He did not think it was out of place to say that those who looked to the laboratory *in vivo* had known for long that this disease was different from poliomyelitis. They were of course glad to have this confirmed by the laboratory, *in vitro*, though there had never been much doubt regarding the dissimilarity of these conditions. As Dr. Strauss had told them, Levaditi had produced the disease by inoculation of the virus into the sciatic nerve. This accomplishment opened up a great field of speculation with reference to the etiology and pathogenesis of many conditions which they had been thinking of as degenerations, such as disseminated sclerosis, where an infection might gain access to the central nervous system as in this disease.

DR. E. LIBMAN said that as regards the value of the animal inoculations for the purpose of diagnosis, only positive results should be used. The test was like many others that are useful in clinical medicine, which were disregarded when negative. As regards the history of the disease, it appeared that it had been known as far back as 1712, and possibly as far as 1580. Levaditi had confirmed all of the experimental studies made by Drs. Loewe and Strauss, and had also produce lesions by intraocular and intrasciatic injections of the virus.

Profuse Hemoptysis in Grippal Bronchopneumonia.—Derrippe analyses a number of cases of this complication in which it was by no means easy to exclude galloping consumption. Daily examinations of sputum should eventually make the diagnosis, along with the coexistence of epidemic influenza and thirdly the state of the patient before the attack is significant. In influenza he is often robust while in galloping phthisis he is pretty sure to be in poor general condition.—*Journal de médecine et de chirurgie pratiques.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Texas State Board of Medical Examiners

November, 1919.

(*Concluded from page* 629.)

GYNECOLOGY.

1. Describe the symptoms and surgical treatment of subinvolution of the uterus complicated by retrodisplacement.
2. Give symptoms, diagnosis, differential diagnosis, and operative treatment of hematosalpinx.
3. Give symptoms, diagnosis, and surgical treatment of interstitial fibroid of the uterus.
4. Define cocygodynia and give symptoms, diagnosis and surgical treatment.
5. Give symptoms, diagnosis and treatment of lacerations of the cervix uteri.
6. Give etiology, symptoms and surgical treatment of prolapse of the ovary.
7. Discuss the differential diagnosis between a large ovarian cyst and ascites; pregnancy and fibroid tumor of uterus.
8. Give the causes of pelvic inflammation, and state its relation to involvement of the ovary.
9. Discuss differential diagnosis between acute oöphoritis and appendicitis.
10. Give differential diagnosis between cystocele and rectocele, and describe operation for cystocele.

SURGERY.

1. A bullet entering the third intercostal space, mid-axillary line of the right side, passing obliquely downward, emerging at the eleventh intercostal space, left mid-axillary line, would pass through what structures?
2. What would be the effect of severing the fifth cranial nerve?
3. Differentiate between concussion and compression of the brain.
4. (*a*) Define pes varus and pes valgus. (*b*) Discuss management of a case, and state age limit beyond which prognosis would be unfavorable.
5. What conditions make it advisable to defer an operation for incipient cancer of the cervix?
6. Describe a Thomas splint, and state when it should be applied in fracture of the humerus.
7. Describe the preparation of the patient for an acute appendectomy.
8. Give treatment of fracture of the lower third of the femur.
9. Describe an operation for umbilical hernia.
10. Describe the operation of ligating the femoral artery in Scarpa's triangle.

HYGIENE.

1. How is typhoid fever disseminated? Give the hygienic management of a case.
2. From a hygienic standpoint, what are the important questions to be considered in the location and construction of a school building?
3. What is meant by immunity and susceptibility?
4. In case the milk or water supply is suspected of being contaminated with some pathogenic germ, how would you prove or disprove your suspicion? What precautions would you advise pending your report?
5. What infectious or contagious diseases are communicated through the medium of the air? What through foods? Give method of combating the latter.
6. What are the characteristics of pure water? How would you render it wholesome when contaminated?
7. Give etiology and prophylais of ophthalmia neonatorum.
8. State the procedure for disinfecting mattresses, blankets and other heavy material of the sick-room.
9. Explain the presence of hookworm in the body. What do you recommend to lessen the prevalence of the disease?
10. As a health officer, what measures would you institute to combat the spread of influenza during an epidemic such as appeared during the winter of 1918-1919?

MEDICAL JURISPRUDENCE.

1. Describe the post-mortem appearance of the lungs in drowning.
2. How would you distinguish between smear of human blood and that of the blood of a lower animal?
3. From the physical appearance of a cadaver, how would you determine the probable time since death?
4. How would you distinguish between a wound made before and one made after death?
5. What evidence would lead you to suspect death by lightning?
6. Upon what physical signs would you make a diagnosis of probable rape?
7. Define (*a*) infanticide, (*b*) feticide.
8. In case of death by same accident of man and wife of approximately the same age and state of health, what is the legal presumption as to survival? Why?
9. Discuss the legal responsibility of person of unsound mind with reference to the execution of wills or contracts.
10. Differentiate morphine poisoning from (*a*) uremia, (*b*) apoplexy.

ANSWERS.

GYNECOLOGY.

1. In *subinvolution of the uterus complicated by retrodisplacement*, the following symptoms may be present: Backache, bearing down pains, a feeling of pressure in the pelvis, constipation, hemorrhoids, frequent or painful urination, leucorrhea, menstrual disturbances as dysmenorrhea or menorrhagia, sterility. There may also be general symptoms, as headache, indigestion, nausea, anorexia, neurasthenia, and general malaise. The treatment consists in first of all correcting such conditions as lacerated cervix or perineum, then in curettage, and replacing of the uterus and retaining it in position by pessaries or tampons, or some operative procedure such as ventral suspension of the uterus or shortening of the round ligaments.

Ventrosuspension: "An incision is made through the abdominal wall in the median line just above the symphysis publis and extending upward for a distance of two inches. The index and middle fingers of the left hand are passed into the peritoneal cavity and gently inserted between the uterus and the rectum. The adhesions are then carefully separated and the fundus of the uterus lifted forward into its normal position. The peritoneum at the lower angle of the wound is seized with hemostatic forceps and drawn into the incision and the first suspension suture introduced close to its divided edge on the left side. The index and middle fingers of the left hand are then passed into the abdominal cavity and the uterus securely held while the suture is passed through the fundus. The suture is now introduced into the fundus directly on a line dividing the uterus transversely into two equal halves and buried one-quarter of an inch deep in the uterine tissue with a distance of about half an inch between the points of entrance and exit. The uterus is then released by the fingers of the left hand and the suture passed through the peritoneum opposite to its point of entrance. The second suture is now passed through the peritoneum on the left side one-quarter of an inch above the first suture. It is then passed through the fundus about one-quarter of an inch behind the first suture, and finally through the peritoneum opposite to its point of entrance. It is not necessary to hold the fundus between the fingers while the second suture is introduced, as the uterus can be easily controlled by making traction upon the free ends of the first suture. After both sutures have been introduced their free ends are seized with forceps and placed on each side of the abdominal incision. The through-and-through sutures closing the abdominal incision are introduced and suspension sutures tied. The first three sutures closing the incision at the lower angle of the wound must be introduced so as to pass completely under the peritoneum at its points of attachment with the fundus, otherwise the weight of the uterus will cause stripping and a large dead space will result which will eventually become filled with serum or blood and suppurate. After all of the incision sutures are introduced the suspension sutures are drawn taut so as to take out the slack and bring the fundus of the uterus up against the peritoneum. The sutures are then tied and their free ends cut off close to the knots. The abdomen is closed and the wound dressed in the usual manner. The fascia is

first united with a continuous suture of catgut and the wound then closed by tying the through-and-through sutures. The sutures in the lower angle of the wound are tied first, and special care must be taken to remove the slack and bring the peritoneum, at its points of attachment with the fundus, snugly against the abdominal wall."—(Ashton's *Gynecology.*)

2. *Hematosalpinx.* "There is nothing distinctive in the symptoms of hematosalpinx; they are usually associated with others due to the condition causing the trouble. The distended tube causes no symptoms in some cases; in others there may be distress or pain in the affected side; the latter may be constant or intermittent, and probably depends mainly upon the associated peritonitis. Pressure symptoms relating to bladder, rectum and other structures are often present. Physical examination gives the same result as in the case of hydrosalpinx or pyosalpinx. Deep pressure in the iliac region of the affected side causes tenderness and resistance. When the tube is much enlarged it may sometimes be felt through the abdominal wall. The diseased condition is best made out on bimanual examination, when the swelling may be easily palpated, the patient usually complaining of pain. When there is inflammatory thickening near the tube it may be impossible to distinguish the latter with accuracy unless it be considerably enlarged. The distended tube may in some cases be felt as an elastic mass; in other cases as a firm swelling lying lateral to, above, or in front of the uterus, which may be much displaced. The mass may be movable, but is generally fixed. . . . Sometimes the fluid is forced from the tube into the uterus and vagina by the bimanual examination."—(Kelly and Noble's *Gynecology.*). The operative treatment consists in abdominal section with removal of the affected tube.

3. *Interstitial fibroids* present the following *symptoms:* Hemorrhage, first occurring as an excess at the usual menstrual periods, and later also occurring between the periods; leucorrhea; tumor, which may reach an enormous size, and may take up a large part of the abdominal cavity; pain, in the tumor and also in the surrounding structures; pressure symptoms in bladder and rectum, and general symptoms such as anemia, edema. The *diagnosis* is made by the history, the symptoms and a physical examination. The uterus is found to be enlarged, smooth, roughly symmetrical in shape. The condition is to be differentiated from pregnancy, displacements, and malignant tumors. The surgical treatment is hysterectomy or myomectomy. Hysterectomy is probably the better procedure.

4. *Coccygodynia* is a painful condition of the coccyx and surrounding structures, the pain being aggravated by pressure or movement. The chief symptom is pain, which is increased on movement, pressure, sitting, defecation. The diagnosis is made on the history of the case, the cause (traumatism, childbirth, neuralgia), and on the physical examination; the examiner inserts his right index finger into the rectum and the thumb externally over the coccyx. and by pressure and palpation detects abnormal sensibility. Treatment consists in removal of the cause if possible, and removal of the coccyx.

5. LACERATIONS OF THE CERVIX. *Symptoms:* Backache and bearing-down pain in the pelvis, leucorrhea, menorrhagia or metrorrhagia, and sterility or abortion. *Diagnosis* is made on the symptoms and a physical examination. A digital examination causes pain, and shows the cervix to be enlarged, indurated, and with everted lips; the eversion can also be seen. *Treatment* depends on the extent of the laceration and the severity of the symptoms. Slight tears may be let alone. Severe cases require trachelorrhaphy, or else amputation of the cervix. Grave pelvic disorders such as pus, adhesions, malignancy, contraindicate operation. The general condition of the patient must be attended to.

6. *Prolapse of ovary:* "Downward displacement without displacement of the tubes and uterus may result from prolonged congestion, inflammation, subinvolution, elongation, and stretching of the ligaments, or violent strain. The symptoms are constant with severe pain, which is increased by movement and at the menstrual period, nausea and indigestion, headache, and nervous disturbances. Bimanual examination reveals enlargement, tenderness, and the abnormal position of the ovary. In uncomplicated cases the ovary may be restored to its proper position by directing the patient to assume the knee-chest posture for ten minutes two or three times daily, or the infundibulo-pelvic ligaments may be shortened through an abdominal incision. Pelvic congestion will require the use of saline laxatives, hot vaginal douches, the application of iodine to the cervix and vaginal vaults, and the use of glycerin tampons. Diseased ovaries should be removed and uterine displacements should be corrected."—(*Pocket Cyclopedia.*)

7.

ASCITES.	OVARIAN CYST.
1. Previous history of visceral disease.	1. No such history.
2. Enlargement comparatively sudden.	2. Gradual.
3. Face puffy; color waxy; early anemia.	3. Facies ovariana. Anemia absent, or later.
4. Patient on back, enlargement symmetrical; flat in front.	4. Asymmetrical until tumor is quite large; prominent in front.
5. Sitting up, abdomen bulges below.	5. No appreciable change.
6. Navel prominent and thinned.	6. Navel usually unchanged.
7. Fluctuation decidedly clear, diffuse throughout abdomen, but avoids highest parts in all positions, and always has a hydrostatic level.	7. Less clear; limited to cyst; not modified by change of position. No hydrostatic level.
8. Intestines float on top of fluid; hence percussion gives clear tympanitic note over the highest parts of abdominal cavity, and dullness in lowest parts for all positions—*i.e.* areas of resonance and dullness change with position.	8. No change in areas of dullness and resonance with change of position. Dullness over cyst. Clear resonant note in all parts beyond cyst limits, *i.e.* in flanks and toward the diaphragm.
9. Vaginal touch detects fluctuation, bulging into vagina.	9. Vaginal fluctuation less clear or absent.
10. Uterus in prolapsed location, but position unchanged. Size and mobility unchanged.	10. Uterus displaced forward or backward, or laterally by pressure of cyst.
11. Hydragogues and diuretics temporarily remove the fluid.	11. Medicines have no effect.
12. Fluid light straw color and thin. Coagulates spontaneously.	12. Fluid light or dark and of varying consistency; albuminous, but does not coagulate spontaneously; may contain colloid matter.

—(From Dudley's *Gynecology.*)

Pregnancy: The tumor is hard and does not fluctuate, is situated in the median line, and may give fetal heart sounds and movements; the cervix is soft, and the other signs of pregnancy are present. The rate of growth of the tumor and the general condition of the patient's health may also help in arriving at a diagnosis.

Uterine fibroid: Menstruation is irregular and sometimes very profuse; absence of the signs of pregnancy; the tumor is nodular, firm, irregular in outline, and while generally placed somewhat centrally is not in the median line, and is not symmetrical; the rate of growth is irregular, being, as a rule, slow, and sometimes extending over years.

8. *Etiology of pelvic inflammation.*

"Since extra-uterine pelvic infection usually originates in the endometrium, its causes will for the most part correspond with those of endometritis. It may, however, start from infection in the intestines, bladder, peritoneum, or vagina. Inflammation of the uterine appendages may be a sequel of the acute infectious diseases. Pelvic hæmatocele may become the seat

infection and be the predisposing cause of a pelvic abscess. Laceration of the perineum and cervix, and other traumatisms of parturition and of surgery, may open the way for the entrance of infection through the blood and lymph channels. The puerperal and traumatic infections more frequently take this route. Infection may be carried to the uterine appendages from external cervicitis. . . . Circumuterine inflammation involves diverse changes in the Fallopian tubes, ovaries, pelvic peritoneum, lymphatics, lymph spaces, veins, and pelvic cellular tissue. Infection of Fallopian tubes or ovaries may have the closest relation with infection of any or all of these structures."—(Dudley's *Gynecology.*)

9.

APPENDICITIS.	TUBO-OVARIAN DISEASE.
1. No previous local disturbances.	1. Genitourinary functions previously disturbed. Usually a history of gonorrheal or puerperal infection.
2. Chill usually absent.	2. Chill may precede fever.
3. Pain in right iliac region, sudden onset, acute, and not radiating to thighs.	3. Gradual onset, pain dull, continuous, and radiating.
4. Fever of variable degree.	4. Fever often entirely absent.
5. Muscular rigidity on right side of the abdomen.	5. No muscular rigidity unless complicated by peritonitis.
6. Inflammatory exudate about appendix three to five days after onset of symptoms.	6. Inflammatory exudate in the pelvis felt by vaginal examination at the onset of the symptoms.
7. Vaginal examination is rarely painful in appendicitis.	7. Always painful in tubo-ovarian disease.

—(Findley.)

10. "*Cystocele* is really a hernia of part of the bladder into the vagina, the vaginal mucous membrane forming its outer covering; or it may be expressed as a deflection of the vesico-vaginal septum toward the vagina. It forms a smooth rounded swelling, which bulges through the vulvar aperture when the patient coughs or strains.

Rectocele is a hernia of the rectum into the vagina, covered by the mucous membrane of the posterior vaginal wall. It forms a swelling resembling that produced by a cystocele, except that it is on the posterior aspect of the vagina. If the finger be introduced into the rectum it can be passed into the pouch in the vagina, and similarly a sound introduced into the bladder can be passed into a cystocele. A rectocele is nearly always associated with a deficient perineum; and, further, cystocele and rectocele are often found together. When this is the case the vulvar outlet, when patient strains, is occupied by two smooth swellings placed one in front of the other: between them the finger can be passed up to the cervix."—(Sutton and Giles' *Diseases of Women.*)

For radical cure of cystocele: "The patient is placed in dorsal position. The posterior vaginal wall is kept out of the way with a weighted speculum. The cervix is drawn down with a bullet-forceps. With a pair of tenacula the sides of the prominence are drawn together in the median line in order to see how much of the wall is redundant and these points are marked with small nicks. Next, the whole surface is put on the stretch between four pairs of forceps—one at each of the sidemarks, one near the cervix, and one at the transverse ridge at the inner end of the urethra. With a pair of scissors curved on the flat, a strip about ¼ inch wide is cut out of the mucous membrane. Similar strips are removed on both sides until an oval is denuded. Finally a running suture of chromicized catgut is passed under the whole pared surface, uniting the edges from side to side." If necessary, a perineorraphy should be done at the same time.

SURGERY.

1. *The structures severed* are, probably: Skin, fascia, serratus magnus and external internal and intercostal muscles, right pleura, right lung, pericardium, heart, left pleura, left lung, diaphragm, peritoneum, descending colon, internal and external intercostal muscles and transversalis and internal and external oblique muscles, fascia, and skin.

2. *Effect of severing the fifth cranial nerve:* Loss of sensation to anterior part of scalp, face, nose, conjunctiva, teeth, mouth, gums, anterior two-thirds of tongue, external auditory meatus; loss of motion to muscles of mastication, mylohyoid, anterior belly of digastric, tensor tympani and tensor palati; loss of secretion of lachrymal gland; impairment of hearing.

3. *Differential diagnosis of concussion and compression of the brain:*

	CONCUSSION.	COMPRESSION.
Onset	Sudden.	Gradual.
General condition	Can be roused.	Cannot be roused.
Pupils	Equal, react.	Dilated, immobile, perhaps unequal.
Pulse	Slow and weak.	Slow, full, heaving.
Respirations	Slow, shallow, irregular.	Slow, deep, stertorous.
Muscular system.	Relaxed (functional paralysis).	Organic paralysis.
Reflexes	Present.	Absent.
Rectum	Incontinenece of feces.	Incontinence of feces.
Bladder	Incontinence of urine.	False incontinence.
Temperature ...	Subnormal, equal on the two sides.	Subnormal, rising in late stages; may be unequal on the two sides.

—(*Aids to Surgical Diagnosis.*)

4. *Pes varus* is a form of club foot in which the anterior half of the foot is adducted and inverted, and the inner side of the foot is raised, the patient walking on the outer side.

Pes valgus is a form of club foot in which the anterior half of the foot is adducted and everted.

The *treatment* of talipes requires persistent care and patience. In congenital cases the aim must be to rectify the altered position of the bones while they are still soft. The nurse should be taught to manipulate the foot into good position, and hold it so for some time daily as soon after birth as possible. This should be combined with massage of the foot and leg. If the leg is not treated in this way, some operation becomes necessary. In paralytic cases massage and faradization of the paralyzed muscles must be persisted in, and steps taken to prevent deformity by the wearing of special apparatus. If deformity has occurred, division of tendons, fascia, ligaments, and even bones, may be necessary to correct the deformity.

It is, however, only in the early stages that such treatment is advisable. At the age of eighteen to twenty-four months considerable growth of the limb has determined such osseous development as almost forbids one to expect benefit from it, without the exercise of undue force. Hence, if treatment is not commenced till the child is two years of age, and still more if the child has walked or is older, other methods must be employed. Of these, two chief plans have been advocated, viz., tarsectomy and Phelps' operation.—(From Rose and Carless' *Manual of Surgery.*

5. As a rule, it is only in the incipient stage of cancer of the cervix that operation promises the best results.

6. *Thomas's splint:* "This consists of a flat bar of malleable iron, about an inch and a half wide, extending from the lower part of the axilla nearly to the ankle; it is shaped so as to fit the varying curves of the body, and cross-pieces embrace the trunk at the level of the nipples, as also the thigh and the calf; it is firmly bandaged to the body and limb. A patten is

placed under the boot of the sound leg, and the patient allowed to get about on crutches. This apparatus should be worn for at least six months after all signs of active disease have disappeared."—(Rose and Carless' *Manual of Surgery.*) This splint is used for hip joint disease, and for intracapsular fracture of the hip.

7. In an appendicitis case the patient is moved with the utmost care and is prepared for operation most gently, because of the possible danger of rupturing an abscess. In an emergency case no prolonged or complicated method of cleansing can be employed. The abdomen and loins are scrubbed carefully with soap and water, special attention being given to the umbilicus; the pubic region is shaved, the soapsuds are washed away with sterile water, the surface is gently scrubbed with alcohol and then with a hot solution of corrosive sublimate (1:1000), and is covered with gauze wet with the sublimate solution. It is not necessary to "prepare" the abdomen the day before. The patient can be prepared antiseptically the morning of the operation, or can be shaved just before the etherization, and be cleaned when under ether."—(DaCosta's *Modern Surgery.*)

8. "In the *lower third*, when the lower fragment is tilted backwards, a Macintyre's splint, with a long thigh-piece and the knee well flexed, may sometimes be employed, together with a short anterior thigh-piece of Gooch's splinting; but in the oblique type, if the upper fragment has penetrated the quadriceps, operation alone holds out any prospect of bringing the parts into apposition, the muscular fibres being divided to allow the projecting end of the bone to be replaced, and fixed by screws or wire. In other cases the ordinary long splint or Hodgen's will be required."—(Rose and Carless' *Manual of Surgery.*)

9. *Operation for radical cure of umbilical hernia.* "(1) Incise at first through skin and fascia only; the incision is elliptical, with upper and lower ends in the median line, and widest part opposite the greatest width of the hernia. (2) Carefully deepen the wound on one side until the abdominal aponeurosis (sheath of the recti) is reached, aiming to come down upon it a short distance to the outer side of the hernial neck. (3) Having once reached the rectal aponeurosis, similarly expose this aponeurosis and the neck of the hernial sac all around the outline of the ellipse. All bleeding is controlled by clamp and ligature. (4) The hernial sac is now incised and its contents dealt with as indicated. Adhesions are separated. Excess of omentum is ligated and excised. All remaining contents of the sac are returned to the abdomen—and kept in place by a large, anchored gauze pad—which is removed just before the closure of the abdomen. (5) The entire sac, with the umbilicus and the coverings included in the ellipse, is now excised—dividing the peritoneum in an elliptical manner about the neck of the sac. (6) The peritoneum—or the peritoneum and transversalis fascia together—is sutured with interrupted or continuous gut sutures. (7) The borders of the abdominal ring—formed by the sheaths and margins of the recti muscles—are freshened with curved scissors. The edges of the ring are then brought together with interrupted sutures of kangaroo tendon or chromic gut—using either the plain interrupted suture, or the mattress type. (8) The skin and fascia (unless the fascia be thick enough to require separate gut suturing) are sutured with interrupted silkworm gut sutures. (9) The part is then well supported by an abdominal dressing."—(Bickham's *Operative Surgery.*)

10. *Ligature of Femoral Artery at the Apex of Scarpa's Triangle.*—A 4-inch incision is made in the line of the artery (a line drawn from midway between the anterior superior spine and the symphysis pubis to the tuberosity of the internal condyle, the limb being flexed abducted and everted) the center being about 4 inches below Poupart's ligament. The integument and and fascia are divided, the inner border of the sartorius exposed, and the sheath found immediately behind it, the muscle being drawn slightly outwards; the middle cutaneous nerve is perhaps brought into view. A muscular branch to the sartorius may be met with at this spot, and should be separately ligatured. The vein is placed behind the artery, so that the needle may be passed either way, special care being taken to keep it close to the vessel.—(Rose and Carless' *Manual of Surgery.*)

HYGIENE.

1. Typhoid fever is transmitted by contaminated water, ice, or milk; shellfish; stools and urine of the patient; flies, and "typhoid carriers." Its specific prevention depends on the use of the prophylactic vaccine.

To prevent the spread of typhoid fever: Flies should be kept out of the house as far as possible, by means of screens or otherwise; all discharges from the sick person must be disinfected; all utensils, dishes, etc., used by the patient must be thoroughly cleansed, and boiled every day; soiled linen must be soaked in a disinfectant solution before being washed; after each attendance on a patient, physicians, nurses, and others should wash their hands in a disinfectant; thorough sterilization of all bedding, etc., must be performed after the disease is over. Further, each household should boil all water that is to be used for drinking or for washing dishes, etc.; milk should be boiled also; and no ice should be put in water or other drink or food.

2. *Concerning schools:* The school building should be as near as possible to the center of the area which it is to serve; the site should be airy and open, of sufficient size, free from swamps, and somewhat elevated; it should not be too near factories, busy streets, or railways; the soil should be as free as possible from organic matter. The buildings should be so planned that the corners look towards the four points of the compass. In this way the sun will have access to each side and to every room during some part of the day. The building should have as few stories as possible. The walls should be of brick or stone, and should be pointed with cement; the inner surface of the wall should be cemented smooth. The foundations must be solid. The general arrangement will depend upon size of site, number of scholars, and number of required rooms. Fifteen square feet per child should be allowed. Details will have to be considered on: plans, accommodations to be provided, shape and size of class rooms, distribution of rooms, teachers' rooms, corridors, entrances and staircases, playground, ventilation, heating, lighting, and placing of windows, sanitation, lavatories, water supply, drinking water, sewage disposal, removal of refuse, sanitary appliances, and drainage.

3. *Immunity* is the power which certain living organisms possess of resisting infection.

Susceptibility is the condition in which the organisms are particularly liable to cause infection.

4. A milk epidemic is characterized by the suddenness with which it makes its appearance, the sufferers being for the most part attacked at about the same time. The infected houses will be found to have been supplied, almost without exception, by the particular milk vendor whose supply is at fault; but it will occasionally happen that infected houses are discovered to which milk has been supplied by a different vendor, this circumstance being often due to the fact that the vendors on their rounds very commonly buy small quantities of milk from each other. Sometimes valuable corroborative testimony implicating the milk is forthcoming in the circumstance that some of those in the infected households, who have consumed no unboiled milk, have escaped, and that households supplied from the implicated dairy, but in which no unboiled milk is consumed at all, have entirely escaped.—(Parkes' *Hygiene.*)

A thorough examination should be made of the suspected milk (or water), by a competent bacteriologist; and until such examination exonerates the milk, such milk should not be used.

5. *Air-borne diseases:* Tuberculosis, scarlet fever, whooping cough, pneumonia, measles, influenza, meningitis, anthrax.

Food may convey: Typhoid, tuberculosis, anthrax, glanders, erysipelas, septicemia, pyemia.

To combat the spread of infectious or contagious diseases through food, thorough and frequent inspection is necessary, with adequate and prompt punishment of offenders.

6. *Pure water* is colorless, odorless, cool, without disagreeable or salt or sweetish taste, and is free from bacteria, poisons, foreign bodies, etc.

Characteristics of a good drinking water: (1) It should be clear and limpid. Cloudy and muddy waters should be avoided. (2) It should be colorless. A green-

ish or yellowish color is usually due to vegetable or animal matter in solution or to organisms. (3) It should be odorless; especially free from sulphuretted hydrogen or putrefactive animal matter. (4) It should not be too cold, but should have a temperature of from 46° F. to 60°. (5) It should have an agreeable taste; neither flat, salty, nor sweetish. A certain amount of hardness and dissolved gases give a sparkling taste. It should contain from 25 to 50 c.c. of gases per liter, of which 8 to 10 per cent. is carbon dioxide and the rest oxygen and nitrogen. (6) It should be as free as possible from dissolved organic matter, especially of animal origin. (7) It should not contain too great an amount of hardness. A certain quantity of saline matter is necessary, however, to give it a good taste. It should not contain over three or four parts of chlorine in 100,000 parts of water.—(From Bartley's *Chemistry.*)

Domestic water purification can be accomplished by filtration and boiling. But the filter must be kept clean; and after boiling the water should be put in a perfectly clean container and covered.

7. OPHTHALMIA NEONATORIUM.—*Causes:* The gonococcus or some other pyogenic microorganism; the secretions of the mother contain the infecting agent, and transmission may occur directly during parturition, or indirectly by the fingers of physician or nurse, cloths, instruments, etc. *Prophylaxis:* Whenever there is the possibility of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of each eye one drop of a 1 per cent. solution of nitrate of silver, immediately after birth.

8. Mattresses, blankets, etc., should be disinfected by steam, in a proper disinfecting apparatus. If the mattress is stuffed with excelsior or other similar material, the contents should be burnt, and the ticking soaked in some disinfectant and then boiled.

9. *Hookworm* enters the body through the skin, the embryos may also enter the body through the water and food. The infection leaves the body in the feces. *To eradicate hookworm:* All drinking water should be boiled; the hands should be washed before eating; shoes should be worn and none should go barefooted; proper toilet facilities should be provided, and people should not be allowed to scatter fecal matter around; mines should be disinfected with chloride of lime. A campaign of education is needed.

10. To combat the spread of *influenza* needs a wide and intensive campaign of education; where possible patients should be isolated and confined to bed during the period of fever; theaters, churches, and crowds should be avoided during epidemics; "carriers" and those liable to colds should guard against exposure and be careful in matters of personal hygiene such as spitting, sneezing, coughing, etc., in public places; ventilation should be enforced, and overcrowding of cars be checked; colds should not be neglected.

MEDICAL JURISPRUDENCE.

1. *The lungs, in death by drowning:* "On opening the thorax the lungs, gray in color, with reddish staining, are seen to be very voluminous, a condition known as ballooning, partly due to infiltration of the lung tissue with some of the medium in which drowning took place, and partly to true edema. The lung substance is inelastic and pits on pressure. On section, fluid and froth resembling that found on the lips exude from the divided air passages. Minute subpleural hemorrhages are not infrequently present, and the pleural cavities may contain fluid."—(Quain's *Dictionary of Medicine.*)

2. It is probably not possible to distinguish absolutely human blood from that of other mammals by examining a smear. By careful measurements of the red corpuscles under the high powers of modern microscopes, human blood can be readily distinguished from that of *some animals;* but in other cases, such as the differential diagnosis between the blood of a man and that of a dog, there is no absolute certainty.

3. *From the appearance of a cadaver to determine the probable time since death:* "It probably will be impossible in the vast majority of cases to make any very definite statement as to the elapsed time, but certain inferences may be drawn: (1) If the body be somewhat below normal in temperature but still higher than the temperature of the surrounding air, if rigidity be commencing about the jaws and eyes, death probably occurred from fifteen minutes to five hours previously. (2) If temperature be entirely absent from the body, rigor mortis present and complete, this time would extend from twelve hours to three or four days. (3) If rigidity is complete and cadaveric lividity is marked, death probably occurred from one to four days previously. (4) If evidence of beginning putrefaction is found, rigor mortis has disappeared, and the body has been exposed to the ordinary temperature of the season; in *summer,* death probably occurred from five to eight days previously, but in *winter* from eight to twenty, according to the temperature."—(Dwight's *Medical Jurisprudence.*)

4. A *wound inflicted during life* is generally characterized by hemorrhage, coagulation of the blood, eversion of the edges, and retraction of its sides. It may also be inferred that the wound was inflicted during life if any of the following are noticed: The presence of inflammation, swelling, pus, or gangrene on the edges of the wound, or if there is any sign of beginning cicatrization.

5. *Post-mortem appearances:* "In those cases of sudden death by lightning in which the body is left in the position occupied at the time of the shock post-mortem rigidity comes on at once. In other cases it may be slower in its onset, but usually is rapid as compared with death from ordinary causes. The conditions found after death from electricity are not consistent; neither are they such as in unknown cases would establish the case of death. Many observers have reported the rapid following of decomposition, but there seems in fact to be little evidence that such is the fact. The heart may be filled with blood, which may be liquid or clotted. The blood is usually dark, but a case has been reported in which it was of a 'rosy, vermillion' color. There is usually a passive congestion of the various organs, including the brain, and small hemorrhages into its substance have been found. Small superficial hemorrhages are usually found scattered over the surface of the lungs and heart."—(Dwight's *Medical Jurisprudence.*)

6. "Medical testimony in cases of rape has usually to do with three conditions: (1) The presence or absence of bruises, lacerations, or other signs of injury upon or about the genital organs. With regard to the evidence of lacerations of the hymen, it must be remembered that a certain number of hymens are so elastic as to permit of intercourse without laceration. (2) The presence or absence of spermatic or bloodstains upon the person or clothing of those concerned, and the presence or absence of spermatozoa in the vagina. (3) The presence of venereal disease in one or both."—(Dwight's *Medical Jurisprudence.*)

The physician can *never be certain* that rape has been committed on an adult, because the element of "volition" enters into the case. All he can do is to give evidence on the lines indicated above, and leave it to the jury to decide to what extent the complainant was "willing."

7. *Infanticide in a medicolegal sense* is the murder of a newborn child, which has a separate existence from its mother.

By *feticide* is meant the unlawful destruction of a fetus before it is born.

8. *Presumption of survivorship* in this case is in favor of the man. "While formerly it was held that where several persons died as the result of the same accident or condition, the presumption was in favor of the physically strongest, it is now generally accepted that there is no artificial presumption in cases of this nature. The question is one of fact decided by the evidence; the elements of strength, age, and sex very naturally have an effect on the decision, how great an effect depending upon the other conditions present and the character of the catastrophe. It is in fact usually held that when the death of a number of individuals occurs under the same circumstances with an entire absence of other evidence, it is to be presumed that in individuals of the same age the stronger outlives the weaker, that the young, strong adult outlives the aged and infants. Decisions upon these points have varied in different States and in different countries."—(Dwight's *Medical Jurisprudence.*)

9. "It is usually understood that the courts require

a less degree of mental capacity in making a will than in any of the ordinary civil duties. People with insane delusions, having made a will which is just and reasonable, have been held as having testamentary capacity, and wills made by patients confined in insane hospitals have been in several instances allowed by the courts. The law ordinarily requires that the testator shall be sane at the time when the will is drawn, so that temporary delirium or intoxication would, for the time being, disqualify him. It has also been held that the presence of disease would not invalidate his will, but that delirium or stupor resulting from such disease would."—(Dwight's *Medical Jurisprudence.*)

10.

APOPLECTIC COMA	UREMIC COMA	MORPHINE POISONING
Deep coma; sudden onset. If any injury, only a scalp wound.	Deep coma. Slow onset unless convulsions have preceded the coma.	Can be aroused unless very deep.
Pupils unequal or dilated. Contracted in hemorrhage into the pons.	Albuminuric retinitis.	Pupils contracted to pinpoint size.
Pulse full and slow, often arteriosclerotic high-tension pulse.	Pulse rapid.	Pulse rapid, may be irregular.
Respiration slow and irregular.	Respiration frequent and irregular.	Respiration very slow—may be 6 to 8 per minute.
Urine contains trace of albumin, but may be same as in uremia.	Urine shows albumin, casts, and low urea percentage.	Normal.

—(From Eisendrath's *Surgical Diagnosis.*)

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

INFECTIOUS DISEASES. By CLAUDE BUCHANAN KER, M.D. 627 pages with illustrations. Published by Oxford University Press, London.

OXFORD MEDICINE. Edited by HENRY A. CHRISTIAN, M.D., and SIR JAMES MACKENZIE, M.D. Volume I. 923 pages with illustrations. Published by Oxford University Press, London.

PLASTIC SURGERY OF THE FACE. By H. D. GILLES, M.D. 408 pages with illustrations. Published by Oxford University Press, London.

MASSAGE AND EXERCISE COMBINED. By ALBRECHT JENSEN. 93 pages with 86 illustrations and deep breathing exercises. Published by the author, 220 West 42d Street, New York.

THE SYMPATHETIC NERVOUS SYSTEM IN DISEASE. By W. LANGDON BROWN, M.D. 101 pages with illustrations. Published by Oxford University Press, London.

THIRTY-FIFTH ANNUAL REPORT OF THE DIRECTORS OF THE MONTEFIORE HOME AND HOSPITAL. (1919.) 99 pages with illustrations.

THE THEORY AND PRACTICE OF MASSAGE. By BEATRICE M. GOODALL-COPESTAKE. 265 pages with illustrations. Published by Paul B. Hoeber, New York.

THE INDUSTRIAL CLINIC. Edited by EDGAR L. COLLIS, M.D. 239 pages with illustrations. Published by William Wood & Company, New York.

MENTAL DEFICIENCY. By A. F. TREDGOLD, M.D. 531 pages with illustrations. Published by William Wood & Company, New York.

EXOPHTHALMIC GOITER AND ITS NONSURGICAL TREATMENT. By ISRAEL BRAM, M.D. 438 pages. Published by C. V. Mosby Company, St. Louis.

Therapeutic Hints.

Quinine by Mouth.—W. H. Willcox holds that cases of malaria where the general condition of the patient is good and there is no marked enlargement of the liver and spleen, and no marked anemia or jaundice (usually mild benign tertian or quartan infections) call for the oral administration of quinine only. After the treatment of the attack of malaria by a week's course of quinine 30 grains daily, subsequently for the next three weeks it is usually advantageous to give a smaller daily amount of quinine combined with arsenic and some suitable tonic. For this he recommends the following:

℞ Quinine bihydrochloridi.....10 gr.
Acid, hydrobromic, dilute.....10 mm.
Liq. arsenic hydrochlor..... 3 mm.
Syrup glycerophosph. co. B.P.C..1½ dr.
Aq. chloroformi, ad..... 1 oz.

Twice daily after food.

Afterward for a month the mixture should be given once daily after food, the arsenic being omitted, and if any anemia is present, Blaud's pills (gr. V) two or three may be given every night.—*The Medical Times*, London.

Hyperchlorhydria.—Rose, discussing the medicinal treatment of hyperchlorhydria, says drugs are used to counteract the effect of acidity by neutralizing the hydrochloric acid and by soothing the mucous membrane and relieving constipation. For average use he recommends the following:

Magnesia usta,
Soda bicarb., ää.....½ oz.

M. et sig.: One-quarter to one teaspoonful one-half to one hour p.c.

Frankly nervous patients are benefited by the following:

Soda bromide.....½ oz.
Glycerin .....3 dm.
Distilled water .....3 oz.

M. et sig.: One teaspoonful in water before meals.—*New York Medical Journal.*

Tinea Tonsurans.—W. P. Elford, as a preliminary step in the treatment of ringworm of the scalp, advises shaving the affected area and cleansing with liquid ethereal soap. The part is then gently and carefully rubbed with a piece of lint which has been dipped in liquor potassæ and dried with a piece of cotton-wool. Next the part is sprayed with ethyl chloride for about thirty seconds and allowed to dry; it is then painted with tr. iodi mitis. This procedure, omitting the ethereal soap, should be carried out morning and evening for three days and once daily during the subsequent four or five days.—*British Medical Journal.*

Miscellany.

Historical Notes on Histology.—In an inaugural lecture delivered by Policard at Lyon in the histolgoical course (*La Presse Medicale*, June 5, 1920, xxviii, 37), the author alludes to Jannsen's microscope, which appeared at the close of XVI. century and which was followed by the epoch-making work of Malpighi. The latter's reputation in his day is hard to visualize now. He was known as "the eye of Italy" and "Malpighi the Lynx." He was not, of course, a mere microscopist, but subjected everything to microscopic control. His discovery of the blood capillaries and circulating blood placed him second only to Harvey. His position as father of minute anatomy is unassailable. He was not a mere laboratory man, for he held, among other honors, the appointment of chief physician to the Pope. Credit as the first histologist of eminence must, however, be shared with Leuwenhoek, who to-day would be termed an amateur scientist. His use of the microscope extended far beyond the animal tissues and his title is really the "first micrographer." Bichat followed and had the advantage of the early chemical studies of Lavoisier. According to Gley it is Bichat who should be termed the founder of modern histology as well as of general anatomy, physiology, and human biology. The discovery of the cell was not made until long after by Schwann, and it is of interest to note that as professor in the University of Louvain this scientist is claimed by the French. A chair of histology was not established at Paris until 1862. Charles Robin and Ranvier, the early incumbent, were constantly engaged in controversies, and Ranvier founded experimental histology and wrote a text book on histology technique. Other French contributions to his science were made by Nageotte, the successor of Ranvier, whose "cell" is well known, and by Carrel in his experiments on the proliferation of tissue cells *in vitro*.

Blind to "See" by Ear.—Dr. Max Herz of Vienna has invented a system for the blind, and partially blind, which substitutes sound for touch, and which is read on phonograph records, by hearing, instead of on paper by touch. He calls the system "Typophonia." Dr. Herz came to this country at the request of a group of individuals and organizations interested in the welfare of the blind. His first demonstration in Baltimore, before an assembly of instructors for the blind, is reported to have been received with enthusiasm. The system is based on an alphabet devised by Dr. Herz from the Morse telegraphic code, the dashes being eliminated and the dots used in various combinations. A phonographic record is made of the subject matter, and the record is placed on an instrument, similar to a phonograph, which is equipped with a sound box. The blind person, after becoming familiar with the alphabet, is able to read by ear, instead of through the fingers, as in the braille or raised-letter system. A "typophonia" library, it is claimed, would occupy very small space and would be relatively inexpensive.

Contract Practice in Old Spain.—Doctor Diego Antonio de Robledo y Mendez was a resident of Coria in Spain, a practitioner of both medicine and surgery, physician to friars, and surgeon to hospitals. By reason of a vacancy he was offered the position of physician in chief to the Friars of Guadelupe for three years. The compensation was 6,600 reals a year, a residence, an assistant and medicines, two pigs, twenty-four bushels of wheat, twenty-four bushels of barley, etc. Only the first year of service was compulsory. The date of the document was November 12, 1673. Apparently he filled the contract with renewals for seventeen years, bringing his service up to 1690. During the first year of his contract he lost his wife, but remarried in 1675. A son and namesake, a recent graduate in medicine, also died during his incumbency. The account of this practitioner in *La Medicina Ibera* of May 8, xi, 131, states further that he was educated at Salamanca and that he published a work entitled *Compendio Cirurgico* at Barcelona in 1686 which went through six editions between 1686 and 1733. According to some of the Spanish historians he seems to have anticipated Boerhaave in teaching anatomy by regions. He also is said to have been the first surgeon to describe curved needles for ligating arteries, which were introduced by his colleague Fernando Diaz, whom he eulogized as a great surgeon. With the latter he lived on terms of friendly intimacy. Robledo seems to have done no private practice in Guadelupe, where Diaz was settled, but may have reserved the right to practice in his home town of Coria, where he continued to reside after the expiration of his contract.

Death of Armand Gautier.—This celebrated biochemist has recently died at the age of 82. His name may perhaps mean more to the former medical students of the world, so far as medical chemistry —as it was formerly called—is concerned, than any other, by reason of his text-books which went through many editions and translations. His father was a Montpellier physician and his mother died during his early childhood. He was handicapped as a student and always afterward by the condition of his eyes. His first masters in chemistry were Bérard and Béchamp. At Paris he also devoted two years to the study of mathematics and physics and was thus well equipped for the career of a modern chemist. He took his medical degree at Montpellier and obtained his licentiate in physical sciences in Paris, later, after a term in Wurtz's laboratory, acquiring the full doctorate. He continued his labors under Wurtz and Schutzenberger, the two eminent Alsatians; and had much experience as war chemist in 1870. Just after the conclusion of the war with Prussia, Wurtz had him appointed to the first chair of biochemistry created in France, and he at once distinguished himself by the discovery of ptomaines, leucomaines, etc., beating Selmi in this feat by a few weeks only. A very active period of writing followed which placed him in the front rank of biochemists, and on the death of Wurtz in 1884 he succeeded him as faculty professor of chemistry in the medical department of the University of Paris. He continued his publishing activities and so numerous and important are his writings that it is difficult to single out any one particular achievement. Perhaps his work in organic arsenical compounds was the most significant, he thus paving the way for Ehrlich.

A NEW AND SUCCESSFUL DIAGNOSIS AND TREATMENT OF CANCER.

BY WILLIAM F. KOCH, PH.D., M.D.,
DETROIT, MICH.

THE mortality from cancer has not been changed essentially by all the treatments ever used to combat it. The death rate still stands one out of eight for females, one out of fourteen for males, dying over forty. So far as the efficiency of the various treatments for cancer is concerned then, we make this observation, that no treatment yet devised meets the essential pathology of the disease.

It is the purpose of this paper to present certain physiological deductions which locate the essential pathology of cancer, and to describe a treatment that simply corrects the pathological condition on a physiological basis, and thus establishes cure. A few histories and microphotographs are selected to illustrate the various phases of the treatment.

In 1912, 1913, 1916 and 1917, I reported* the occurrence of toxic quantities of certain guanidine bases and other products of tissue degeneration in the urines of parathyroidectomized dogs. This finding has since been confirmed by Paton at Glasgow and by other observers. My autopsies showed in these animals extensive antemortem coagulation of the blood and also a coagulation of the tissue cells in the liver, lung, spleen and brain.

Such extensive coagulation of blood and tissues ensuing upon the loss of one physiological substance is suggestive that normal functional tissues are incoagulable so long as they receive and can build into their structure all the elements necessary for functionally co-ordinated activity, and that as soon as this balanced nutrition is disturbed they become coagulable. In this case after parathyroidectomy the tissues had lost a necessary special element and had become coagulated just as blood withdrawn from its endothelial encasement becomes coagulable.

Now, two types of substances are active in the coagulation of drawn blood, the thrombokinase and the thrombin.

The thrombokinase is a product of tissue-cell injury and blood plasma is constructed to have unsaturated affinity for it, so that when this product is liberated it can react with the blood plasma and initiate clotting. Therefore, thrombokinase produces intravascular and extravascular coagulation. This is a physiological function of the plasma to prevent hemorrhage. Likewise the plasma of tissue cells clots by reaction with a product of injury to tissue cells. This function of tissue-cell plasma coagulation serves to wall off destructive processes and also to lay a bed for ingrowth of angioblastic organization tissue, thus preparing for and promoting the healing process. This coagulation process is evidently, then, a highly specialized function in all normal tissues and an activity of their functional substrate.

The type of injury that leads to the production of thrombokinase may be an active, physical or chemical one, or a passive one, as occurred in my parathyroidectomized dogs, where failure to supply certain necessary elements (because of absence of the parathyroid activity) prevented the completion of the restoring of the cell functional substrate, and therefore the elements of this substrate already present, not being usable, were set free and were active as tissue injury or degeneration products, and initiated clotting not only of the tissue cells but of the blood as well.

The condition necessary for the initiation of coagulation in a tissue plasma, then, is the presence of a certain product of tissue-cell degeneration for which the plasma has unsaturated affinity.

The Thrombin. Now it happens in any physiological intracellular function that the initiation of a state of change and the propagation of this state are mediated by different substances, the propagation of the state being carried on by the products of the change induced, whether energy is liberated or not. We observe this in muscle and nerve cell function, and a good example is offered by blood clotting.

The process of clotting having been initiated by the kinase, some thrombin is formed by the clotting process, and this substance propagates the change of state in the fibrinogen. After blood is shed its functional substrate is removed from the nutritional support of its endothelial encasement and therefore is in the predicament comparable to the tissue of my parathyroidectomized dogs, and subject to thrombin activity. As stated above, coagulation of tissue plasma is a function of the tissue and therefore an activity of its functional substrate. The kinase acts on this functional substrate, starting the process; the thrombin, a product of the state initiated in the tissue functional substrate, propagates the process. Thrombin cannot act on an unchanged functional substrate as is illustrated by the fact that it will not change the coagulability of circulating blood where a state of coagulation has not been initiated. It can act only on a plasma associated with a change of substrate.

Since cancer is deficient in functional substrate, at least insofar as any specialized highly differentiated function is concerned, it was suggestive that this variation from the normally constructed sub-

*See Bibliography appended.

strate might constitute a susceptibility to coagulation and therefore to the action of tissue thrombin. That is, the change necessary to induce coagulation existed, but the functional substrate being deficient, no thrombin product could be evolved to propagate a

FIG. 1.—Section taken from the untreated squamous cell carcinoma.

coagulation state throughout the cancer cell plasma, and therefore the cancer cell plasma remained unclotted until it might receive the propagator of the state that virtually existed in it.

In line with this supposition, then, thrombokinase could not initiate coagulation in a cancer cell, although not clotted, being already prepared for the activity of the thrombin.

To test out this hypothesis cancer patients were treated with tissue thrombokinase and with tissue thrombin. Amounts varying from 1/100 grm. to ½ grm. of tissue kinase and tissue thrombin being injected subcutaneously, generally in the patients buttocks, the substance being dissolved or suspended in normal salt solution in from 1 to 10 c.c.

The kinases will first be disposed of.

Quantities of the kinase insufficient to cause extensive intravascular coagulation of the blood, and therefore immediate death in the patient, were found actually to increase cancer growth and, moreover, to cause so great a negative coagulation phase of the patient's blood that hemorrhages were profuse and the continuance of such treatment threatened the patient's life. The site of the injection showed tissue death. Therefore such therapy was discontinued as useless and harmful.

The use of the tissue thrombin, however, brought very different results. Locally, where injected in the hip, no sign of disturbance was produced—no more than if normal salt solution were injected.

There was no change in the patient's blood coagulation time, as the following experiment shows: Fifty mgms. of tissue thrombin were injected subcutaneously into a healthy man of 157 lbs.

	Coagulation Time
Before injection	2 min. 40 sec.
10 min. after injection	2 min. 40 sec.
1 hr. after injection	2 min. 42 sec.
12 hr. after injection	2 min. 40 sec.
24 hr. after injection	2 min. 43 sec.

Fifty mg. of tissue thrombin were injected into a cancer patient who had not had any severe hemorrhage.

Before injection	3 min. 12 sec.
1 hr. after injection	3 min. 20 sec.
12 hr. after injection	3 min. 14 sec.
24 hr. after injection	3 min. 8 sec.

The microphotographs show the effect of the injected tissue thrombin upon cancer cells. These sections were taken from a large squamous cell carcinoma of the neck (Case IV, reported in the *Detroit Medical Journal*, July, 1919). The usual dose of 50 mgms. was given in the hip.

Section I was taken before treatment and shows the normal squamous cell carcinoma. Fig. 2 shows a low power magnification, and the series 3, 4, 5 and 6 show the details of the changes induced after two treatments. The most pronounced changes are firstly, a disappearance of the cells lining the basement membrane. These are the cells closest to the blood supply, the germinal cells of the cancer. Naturally the tissue thrombin reaches them first and they are the first to be destroyed. As rapidly as they disappear angioblastic tissue replaces them. Apparently the carcinomatous clumps are being devoured by angioblastic tissue just as takes place in the development of bone and in the organization of a blood clot. Investigation of the chemistry of these three phenomena reveals that they are essentially the same process. The changes preparatory to organization of the cancer tissue are first as shown in Fig. 6, nucleolysis and a fibrin formation in the cells, and as is shown in Figs. 3, 4 and 5, a swelling of this fibrin which produces a hyalinization of the cancer protoplasm. This is a digestive change in the clotted protoplasm which accompanies the ingrowth of the angioblastic tissue (shown best in Fig. 3 and Fig. 4 at x). Fig.

FIG. 2.—Section from the squamous cell carcinoma, removed 24 hours after the second treatment (low power). The disappearance of the malpighian layer of cells, the hyalinization of the protoplasm, and the disappearance of the nuclei of the remaining cells and ingrowth of fibroblastic tissue are shown here.

7 was taken from a piece of the carcinoma removed after the fourth treatment. It shows the practically complete replacement of the carcimona by fibroblastic tissue. Whatever carcinomatous debris is left has undergone a calcification. This calcification

change also occurs preliminary to bone absorption in the development of bone. Here it occurs in the last remnants of the clotted cancer which have lain unabsorbed sufficiently long to have taken up lime

FIG. 3.—High power magnification of section (Fig. 2), showing chromatolysis, fibrin formation, and hyalin change in the cancer cells. This section shows the ingrowth of angioblastic tissue, the organization of the coagulated cancer.

salts. This change is a conclusive testimony to the complete death of the cancer moreover.

CLINICAL.

The clinical features that accompany this change induced in the cancer are for the first twenty hours after injection practically negligible. There is no change in the heart beat, in the respiration, or in the comfort of the patient. Locally, in the hip where the injection is given, there is no reaction at all. After twenty hours the injected material has been taken up by the circulation and lodged in the cancerous tissues where it now shows its work. The cancerous parts become swollen, more painful than usual, and reflexes associated with the part are augmented and fever develops, especially between twenty-four and thirty hours after injection, generally lasting from two to six hours, and as this subsides the affected parts become smaller and less tender than before treatment, and there is less pain. The patient, however, may be quite tired out for the next day, but the following day finds him much more normal and buoyant. As a rule, after two injections hemorrhages have stopped, not to return, and pain ilkewise, as treatment proceeds, rapidly passes away.

CASE I.—The first case is selected to illustrate the healing of a vesicovaginal fistula large enough to easily admit three fingers following upon the disappearance of the cancer tissue. It also illustrates the usual reaction features. This patient came under my care April 24, 1919, referred by Dr. Walter Hackett of Detroit.

Mrs. B., age 53, housewife. Normal weight, 125 pounds, five years ago. Patient's family state weight at present to be 70 pounds, having been weighed several weeks previously. *Family history*—Father died of cancer of stomach, age 61. Mother died of heart disease, age 57. No history of tuberculosis, insanity, or alcoholism in family. Four children alive and well. *Past history*—Two years ago (1917) patient noted vaginal discharge, which gradually became excessive, odorous and bloody. More notable were the occasional hemorrhages without period of menstruation. This bleeding was initiated by sudden movements, and even came on during sleep in bed. At this time her weight was 107 pounds. In March, 1919, patient was examined by Dr. Garber, Dr. Hurst and Dr. W. Hackett, who gave the diagnosis of carcinoma of uterus. Wassermann, negative; R. B. C., 2,700,000; Hem., 50 per cent.; urine, albumin, trace; sugar and casts, negative.

April 5, 1919, laparotomy and hysterectomy by Dr. Walter Hackett. As much of the carcinomatous tissue as possible was removed, although the subrenal lymph glands were infiltrated. Tissue was examined microscopically, and proved to be adenocarcinoma of endometral origin. On April 30 I found the patient very weak and anemic. She could not sit up in bed without help. It was impossible to get a satisfactory drop of blood by several deep punctures of the finger, and the attempt to withdraw blood by syringe failed, as the vein collapsed. Patient took about 8 ounces of milk per day and very little other food. The pain was severe enough to require between 3 and 4 grains of morphine per day. The discharge was excessive, of strong odor, and accompanied by the escape of urine from a vesicovaginal fistula large enough to easily admit three fingers. At the orifice of the vagina carcinomatous nodules were visible. Moderate but exhausting hemorrhages had occurred several times a week. She was given an injection of 50 milligrams of tissue thrombin in 2 c.c. of normal salt solution, April 30, 1919. Temperature, 96.2°; pulse, 110. The next day, 24 hours after treatment, her temperature rose to 101.4°; the pulse became feeble and 134. The pain in the back and abdomen was intense for 4 hours. Two grains of morphine had to be given by hypodermic injection to control it. The next day the temperature was 97.2°, and in the succeeding night an exhausting hemorrhage occurred. The blood clotted readily. This was the last hemorrhage. May 3 a similar treatment was given. Temperature, 98°; pulse, 120. In 24 hours the temperature rose to 102°, and was maintained for 8 hours. The discharge had increased considerably and had become more acrid. The patient suffered so much pain that 2 grains of morphine were necessary. On May 6 the third treatment was given, the discharge still increasing, but with less odor and no blood, accompanied by less pain than the former treatments. After 24 hours the temperature rose to 101.6°, the pulse to 103. The fever was maintained for 6 hours. The appetite started to improve after this treatment, and in four days she was able to sit up in bed without help. The succeeding treatments brought on similar

FIG. 4.—Shows the same changes as in Fig. 3.

reactions, but each time the fever and pain were less, so that after taking the ninth treatment, June 5, neither pain nor fever could be elicited and the patient has suffered none since, having also discontinued the use of morphine. The discharge had completely disappeared, and the patient was able to walk about the

house and sweep the floor. She then weighed 94.5 pounds. Treatment was discontinued.

On June 30 the patient weighed 112 pounds, a gain of 42 pounds in eight weeks (since treatment was started). At this time there was slight and controllable escape of urine through the

FIG. 5.—Shows the same changes as Fig. 3 and at x the ingrowth of angioblastic buds into a coagulated mass of cancer.

vagina. She was examined in the middle of July by Dr. J. H. Carstens, who stated that he found no evidence of cancer, and the vesicovaginal fistula was closed so as not to admit a finger. This region he found indurated. On August 8 examination was again made and fistula found entirely closed; weight, 116 pounds. She was then active at her household duties. The blood was taken for analysis: R. B. C., 3,970,000; H., 70 per cent.; noncoagulable nitrogen, 29 mgms. per 100 c.c.; alkalinity, 47 c.c., CO_2 per 100 c.c.

The alkalinity was normal and not increased, as is the rule in cancer patients. The noncoagulable nitrogen was normal, hence there was no diminution of kidney function. The patient had no symptoms of cancer, and examination elicited only some slight induration at the region of the previous fistula, which was to be expected as a result of the healing process. She was therefore pronounced tentatively cured, and remained so until November 5, 1919, when she suddenly dropped in an apoplectic stroke and died November 6 of apoplexy. Unfortunately, I was not notified of her death until two weeks later, and then an autopsy was out of the question.

CASE II.—The following case illustrates a variation from the usual type of reaction. Instead of the reaction coming on 24 hours after the treatment, in this case no febrile response occurred until twelve days after the first treatment and seven days after the second treatment. During this period a large carcinoma of the stomach, practically stenosing the pyloris, disappeared.

Mrs. P., aged 58, referred by Dr. Heavenrich of Port Huron, Mich., November 1, 1919. *Family History.*—Father died at middle age of heart trouble. Mother died at 85 years of old age. Brother died of typhoid. One sister died of pneumonia. Two sisters alive and well. No history of tuberculosis, insanity or cancer. *Chief Complaints.*—Pain in abdomen and right back, vomiting and tender mass in upper abdomen.

Past History.—Measles, whooping cough, chickenpox in childhood, well otherwise until present illness. Menses began at 14, have been normal until menopause at 49, were somewhat painful first day or two. Pregnant once; child died in infancy. No miscarriages; denies venereal infection. For past three to four years patient has been troubled with indigestion, pain coming on from two to three hours after eating, with burning pain and eructation of gas. *Present History.*—On this subject Dr. Heavenrich of Port Huron writes as follows: "She was taken ill August 1, 1919, with what was diagnosed gallstone colic. Needed opiates for relief of pain. During the following six weeks had repeated attacks—pain, nausea, jaundice. Was seen by several doctors, all of whom agreed in diagnosis and need of operation. I first saw her in September in one of these attacks. I found her emaciated and anemic, suffering severely with typical gallstone colic. Deep jaundice over entire body. Itchy skin, clay stools, and vomiting bile. Unable to retain any food. Temperature 98.4°; pulse, 112. Abdomen so tender as to make palpation impossible. I also advised operation and was requested to do so at once. I had her removed to the hospital, where she was operated on the following morning by Dr. Aldridge and myself. To our surprise we found the liver and gall bladder perfectly normal—no stones, no thickening of duct walls, etc. But the lesser curvature of the stomach was one large sausage-shaped tumor, hard in consistency, with some nodules at various spots. So much of the organ was involved and the patient was in such a weakened condition that we were both of the opinion that gastroenterostomy or any modification of such operation would be of no avail. We closed the wound and about November 1 sent her to you. At this time (August 8, 1920) she appears to be in splendid health, does her own work, and eats everything, and certainly is grateful to you."

On admission to the Womens' Hospital, Detroit, November 1, 1919, her weight was 119 lbs.; R.B.C., 3,100,000; H. 60 per cent.; Wassermann negative, urine negative to albumin, casts and sugar; volume 7 oz. in 24 hours. Stools loose, scanty and tarry, occult blood negative. Retention of food very slight, apparently all food ingested was vomited. Physical examination revealed mass in epigastrium raised to a level of an inch and one-half above the costal level. Palpation showed mass to be hard and very tender, which prevented outlining its borders. Light percussion showed the dullness to extend to the umbilicus.

For descriptive purposes her stay of forty-one days at the hospital is divided into three periods. The first, of eleven days, was reaction-free, although an injection of 50 mgm. of tissue thrombin was given on the first and fourth days. Temperature running from 97° to 98°, with at times severe abdominal pain and vomiting the daily food ingested. The second period started on the eleventh day, seven days after the second treat-

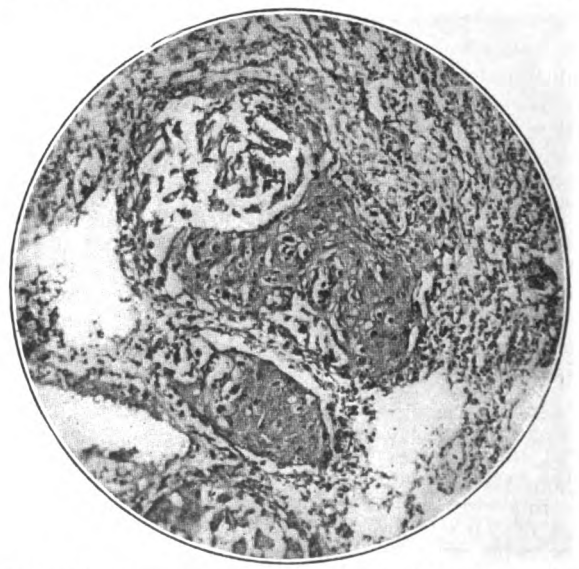

FIG. 6.—Shows same changes as Fig. 3, but more particularly the fibrin formation in the cancer protoplasm.

ment, with a fever of 102°, dropping in 36 hours to normal and rising for three successive days to 100°. On the third day of this period (the fourteenth day), a third injection was given, followed in 48 hours by a fever of 102°, which returned to 99° in the course of 24 hours, rising again for four more days to

100° and again to 102° for a number of hours. After a rest of two days she was given another treatment, and in 48 hours another fever of 102° was elicited, returning to normal within 24 hours and remaining there ever since. During this period there was much pain in lower right chest and shortness of breath and cough coming on in daily spells and accompanying the epigastric pain. With the disappearance of the fever at the end of this period all pain left. During the last six days there was no vomiting, nor has there been since. The appetite and digestion rapidly improved, and no epigastric mass was evident on inspection. The third or convalescent period of 14 days was painless and without vomiting or gastric distress, the patient taking the regular tray. Temperature running 98° to 98 3/5°. She rapidly gained strength. On the sixth day of this period a treatment of 50 mgms. was given, without any focal or febrile reaction. Examination of the epigastrium showed neither dullness nor rigidity and only slight tenderness. On deep palpation a suggestion of a tumor rather soft and not outlinable was found. She was kept in the hospital for eight days longer and her abdomen again examined. This time the examination was entirely negative. R.B.C. 4,000,000; H. 80 per cent.; weight, 126 lbs. Blood analysis: Non-coagulable nitrogen, 43 mg. per 100 c.c. Alkalinity, 40 c.c. CO_2

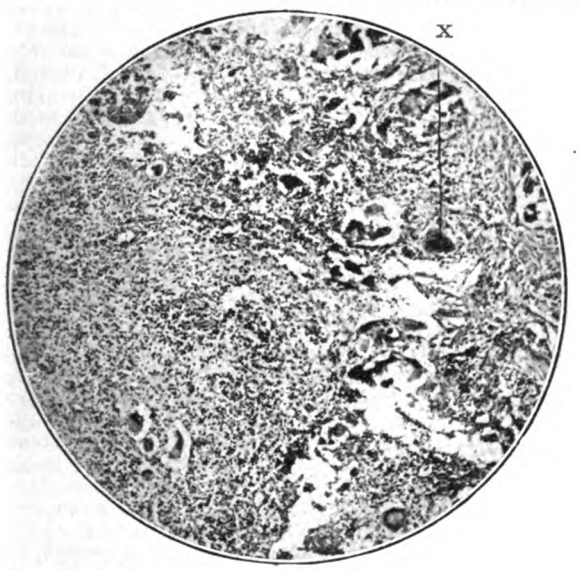

FIG. 7.—Low power view taken from a section removed after the fourth treatment, showing the fibroblastic replacement of the killed cancer. Also calcification (x) of as yet unabsorbed debris.

per 100 c.c. She was discharged, tentatively cured.

In March, 1920, the patient was requested to present herself for another examination. She appeared to be in splendid health, had a good appetite, ate everything, and weighed 142 lbs. She complained of slight distress after eating for the past week. She was given two more treatments four days apart, with slight focal reaction and a temperature of 100.2° in response to the first treatment, but no febrile reaction to the second. Within a week the indigestion had disappeared and has not returned to date. In July, 1920, her weight was 152 lbs., and she reported no trouble. Examined again August 1. Weight 159 lbs. She is still in excellent health.

CASE III—This case, with its control case and the case following, are submitted to illustrate the effect of doses of various amounts of tissue thrombin. These three cases came from the same region in Michigan, two from Bay City and one from a neighboring town. The first two are in patients of normal weight of about 200 lbs., the third a normal weight of 160 lbs. The first two have similar carcinomata of the large bowel, and the third a gastric cancer.

Mrs. B., referred by Dr. H. J. Meyers of Saginaw, Mich., January, 1920. *Family History.*—Mother died of heart failure at the age of 69 years. Father died of cancer of stomach, age 71. Two sisters died of tuberculosis. She has one son living and well. *Past History.*—Scarlet fever at 8 years, and a cervix repair operation about 25 years ago. *Present illness*, reported by Dr. Meyers, as follows: "Mrs. G. B., housewife, age 52, was first seen by me in consultation with her home physician in Bay City. This was in October, 1919. The story was as follows: A few days before, Mrs. B. had been very suddenly seized with intense abdominal pain, most marked in the upper left quadrant. There was nausea but no vomiting. The pulse became rapid and weak. There was great prostration, and the patient bordered on collapse when Dr. K. arrived and administered morphine and stimulants. This attack occurred about 3 P. M. The next morning at 2 o'clock the patient had a large hemorrhage from the bowel. Two hours afterward a second bloody stool was passed. There was no recurrence of the pain. At the time of consultation, a few days after the above attack, inquiry elicited the fact that the patient, who had been a very strong, robust woman, had lost 20 lbs. during the last few months, and that she had had a feeling of weight distress and pain in the left upper quadrant of the abdomen. Examination failed to disclose more than a feeling of rigidity over the left rectus muscle. There was also a tender area that could be mapped out on deep pressure, but no tumor could be definitely found by external diagnostic methods. Rectal investigation for a possible source of the hemorrhage was negative. *X*-ray investigation of the upper digestive tract with the bismuth and barium meals was negative, but tracing the meal through the colon we were impressed by the fact that there was marked angulation at the splenic flexure of the colon, and that shadow seemed to thin out markedly at this point, and also that the appearance of the chemical in the descending colon was appreciably retarded. A tentative diagnosis of probable malignant trouble was made and an exploratory laparotomy was advised. On November 4, 1919, the operation disclosed the following pathology: A large irregular fusiform tumor situated at the splenic flexure of the colon. This mass was in and surrounding the lumen of the bowel, and was bound down to the posterior abdominal parieties. The mesocolon and mesenteric glands were infiltrated. The entire mass was practically inaccessible to surgical interference, and after due investigation it was decided that the tumor was inoperable. The abdomen was closed and the patient returned to bed. When the patient regained consciousness there was an excessive amount of pain resembling in character the pain she previously suffered just previous to the hemorrhage at the beginning of her trouble. The subsequent convalescence was uneventful, and she was then referred to you for treatment."

Physical examination December 8, 1919. Weight 201 lbs. Urine negative to albumin and sugar. R.B.C., 3,400,000; H. 70 per cent.; stools tarry. Wassermann negative; temperature 97°-98°. Inspection revealed upper left quadrant of abdomen to be fuller than other side. Palpation revealed same to be very tender, rigid and with dull percussion note. Patient complained of inability to lie on the left side or to touch same with her arm, and also of severe pain most of the time in that region.

Treatments of 5 mgms. each were given on December 20, 22, 29, 30, and January 2. The reaction temperature at no time rose above 99°. On January 5, 50 mgms. were given. This was followed in 24 hours by a fever of 102.5°, accompanied by the severe focal pain that had previously called attention to her sickness. Twenty other treatments were given up to July 20, each of 5 mgms. In no case did a reaction follow with a fever of over 99.4°. The last four treatments elicited no reaction whatever. On January 20, she could lie on her left side and the tenderness to pressure was very much diminished. On February 9 the soreness had entirely disappeared. By May 12 her stools had lost the tarry color. On July 6 palpation of the abdomen, as deep as the posterior parieties, elicited neither tenderness nor pain, and no suspicion of a mass could be found. She weighs at present 219 lbs., and is apparently in perfect health.

CASE IV.—As a control case Mr. H., referred by Dr. Tupper of Bay City, is selected. Occupation, banker;

age 56; normal weight about 200 lbs. *Family History.*—Negative to cancer. *Past History.*—Besides fevers of childhood, was well until present illness. This came on early in 1919 with constipation, pain and tenderness in lower right quadrant of abdomen. Iliocolostomy was performed by Dr. Tupper in November, 1919, to sidetrack a large obstructing carcinoma of the ileocecal region. Examination December 1, 1919. R.B.C., 3,200,000; H., 60 per cent.; weight, 162 lbs.; pulse, 130; temperature, 95.2°; tarry stools. He was quite exhausted from his trip to Detroit. On December 3, the first treatment of 25 mgms. was given. On the next day he tried to walk but suffered a sinking spell. Twenty-four hours after treatment was given the temperature remained at 97°, pulse 110. Succeeding treatmentss of 50 mgms. of tissue thrombin given at intervals of three and four days were followed by temperature elevations which gradually came, after the ninth treatment, up to 102.5°. Two more such treatments were followed with a fever of 101.5° and 100° respectively, and the following treatment elicited no reaction at all. During this period the tenderness gradually left, and on December 31 examination could elicit neither tenderness, rigidity, pain nor mass. The patient was able to go about as he pleased, having gained 45 lbs., and holding a temperature of 98°-98.4°. Treatment was then discontinued. In March, 1920, three trial treatments of 50 mgms. were given in one week, with neither febrile nor focal reaction, abdomen apparently normal. Weight 205 lbs. R.B.C., 4,200,000; H., 85 per cent.

The case of Mrs. B. shows that small doses are effective, but require a longer period and a larger number of treatments. This case gave the usual response to the ordinary dose. The control case of Mr. H. demonstrates that after the exhaustion had been overcome, the 50 mg. dose of tissue thrombin brings on the usual reaction, with fever at 102°, and that with larger doses fewer treatments are required.

CASE V.—The following case demonstrates the activity of large doses as 100 mgms. of the thrombin:

Mrs. Z., age 53, referred by Dr. Friedlander, March, 1919. *Family History.*—Father died of dropsy at age of 71 years. Mother died of rapidly growing tumor of uterus when 71 years old. One sister died of cancer, age 65; one brother died of cancer of the stomach at the age of 63 years. Two brothers are living, one well, age 52; the other has heart trouble, age 56. Four children, one died as baby of "cramps," one boy died of scarlet fever, age 7½ years; two children living and well—a boy, 24; a girl, 23. *Past History.*—Scarlet fever at 6; la grippe and bronchitis at 25; repair operation after childbirth, age 34; hysterectomy for malignancy, age 47; otherwise well until 14 years ago. Had burning pains in stomach after and before eating, vomited often and occasionally vomited blood, one-half pint at a time. Stomach improved somewhat until present illness. *Present History.*—February 4, 1918, had attack of severe pain, doubled up and not relieved without morphine. The spells came on every two weeks until March 24, 1919. At that time her weight was 126 lbs. Gastric analysis at this time showed absolute achlorhydria. The stools were tarry, and practically all food ingested was vomited.

On March 24, an exploratory operation by Dr. Friedlander showed a very large mass involving the liver, stomach, gall bladder and intestines. From its physical characteristics it was diagnosed carcinoma of pyloric origin by Dr. Friedlander, Dr. Israel and some other surgeons who happened to be present. No specimen was removed for microscopic confirmation because there could be no doubt of the diagnosis, and belief in the inadvisability of such procedure.

Treatment started April 8, 1919. At this time the patient could take small quantities of liquids and even this diet caused vomiting. Examination revealed a hard triangular area 11 c.m. long and 12 c.m. wide at its base just below the costal margin and extending over the epigastrium. This area was very tender and the seat of the pain. At first 50 mgms. of tissue thrombin was injected. In 24 hours a fever of 102.2°, lasting 8 hours, was elicited. There was very severe pain and vomiting of much mucus. Six days later a second injection, this time of 100 mgms., was given, followed in 24 hours by fever of 104.2° and lasting 10 hours, accompanied by very severe pain in abdomen and aching in limbs and head. Every "bone felt broken," she complained, and there was vomiting of mucus. Four days late 200 mgms. was injected, the fever rose in 24 hours to 105.4°, and after an hour dropped to 104.4°, when it soon dropped to 103° and remained for 14 hours. The pain was again severe and the universal aching was very distressing. She was then given a vacation of two weeks. On her return she weighed 136 lbs., was much stronger, having eaten fairly well and vomited mucus only twice, but no food, during the two weeks. The tenderness in the abdomen was much reduced and the tumor palpable through the abdominal wall felt about the size of an orange. She was then given three treatments of 50 mgms. at three-day intervals. The reaction started 24 hours after treatment, fever being 103.5°, 101° and 100.2° respectively, and with less severe pain and no vomiting. After the last treatment the mass on very deep palpation was about the size of an egg. Five days after the last treatment the patient developed a tetanoid condition, with stiff neck and laryngeal spasm which I cannot explain unless it was due to some guanidine products absorbed from the killed cancer or possibly to a mild tetanus infection. The former diagnosis was favored by those physicians who examined the patient. This lasted for four days, but recovery was complete only after two weeks. At this time no mass was palpable on examination by Dr. Friedlander, Dr. Israel, Dr. Watkins and myself. She returned home in June, 1919.

In October, 1919, I examined her. No palpable mass or tenderness was found. She had no pain up to that time, was doing all her work, never felt fatigued, and her digestion was perfect. Stools, normal color. Weight 149 lbs. A sample of gastric juice was taken showing 0.9 per cent. free HCl. R.B.C., 4,450,000; H., 90 per cent. Blood analysis: Noncoagulable nitrogen, 33 mgms. per 100 c.c.; alkalinity, 52 C.C. CO_2 per 100 c.c.

March, 1920, weight 161 lbs., feeling perfectly well, no palpable mass or tenderness. She was given two injections of cephalin (0.5 gm.), which I believe promotes cancer growth. This was done to light up any hidden cancer tissue, if it were present. Patient remained well until June, 1920. Two more injections of cephalin (0.5 gm. each) were given. I heard from from her July 29, 1920. Weight 163 lbs., feeling well in every way, and her stomach perfectly well except that she complained of having had pain in lower abdomen at times and occasional diarrhea, which at present has nearly cleared up. She will be examined in due time and treated with tissue thrombin, if required.

This case illustrates, in support of the former, that the size of the dose determines the extent of the reaction, and that with larger doses fewer treatments are required.

These experiments show, then, that the tissue thrombin does not behave as a ferment but acts quantitatively. Moreover, the chemical properties are not those of a ferment. This is a matter of some interest, since ferments can induce the production of antibodies when injected into the animal body. Nevertheless the conversion of at least two pounds of cancer tissue by less than ½ gm. of tissue thrombin qualifies this substance, in some measure, as a catalyst.

CASE VI.—This case is presented, with the case following, to differentiate, by the type of reaction, a gastric carcinoma and a gastric ulcer; that is, a carcinoma and a precarcinomatous condition.

Mrs. S., age 72, referred by Dr. Watkins of Detroit. May 9, 1919. There is no history of cancer, tuberculosis, or insanity in the family. *Past history* shows, besides measles in childhood, a history of gastric ulcer, indigestion, intense hyperacidity, several hemorrhages 15 years ago, and the development since that time of a

peculiar arthritis in the fingers and in the bones of the feet, which more recently made walking difficult and limited digital motion. *Present illness* started with abdominal pain after eating and the inability to retain food for several weeks, and, in addition, several severe gastric hemorrhages repeated at intervals of a few days. She was admitted to Grace Hospital May 6, 1919, after a severe gastric hemorrhage. The diagnosis was made by Dr. Watkins from the clinical history, *x*-ray findings and physical examination as follows: Carcinoma of the posterior wall of stomach, involving the pylorus and causing considerable stenosis. He also gave a prognosis of only a few days to live. Examination of the abdomen showed some tenderness in the epigastric region, but no mass could be palpated. Because of the anemia a transfusion of 500 c.c. of blood was given. This raised the blood count to 2,850,000, and the hemoglobin to 37 per cent. The Wassermann reaction showed slight inhibition. Patient had been having a cardiac irregularity for some time. At this time her pulse was irregular and weak, and under the control of digitalis. She was able to take a half ounce of milk and cream hourly.

She was given an injection of tissue thrombin (50 mg.) May 9, 1919. In 24 hours a fever of 101.2° developed, and the abdominal pain was intense, the heart showing signs of failure. With sufficient stimulation the heart was kept going, and three days later another treatment was given of 50 mgms. tissue thrombin. In 24 hours the temperature rose to 102.8°, with considerable gastric pain for six hours, and some cerebral disturbance, perhaps due largely to the anemia, and with pains over the body as in la grippe, for 12 hours. This typifies the reaction in this patient. She received four more treatments at intervals of several days, to which the response was less for the second last, and *nil* for the last treatment. During this period of four weeks' treatment there was no hemorrhage, nor has there been any since, and the diet was increased to the regular tray. The pain rapidly disappeared, and she has not vomited nor had any hemorrhage since treatment started. In August, 1919, she was given a trial treatment, but neither pain nor fever could be elicited. She remains well to date, a period of 15 months, and is up and about, feeling better than she did five years ago, and without gastric symptoms, and the gainer of considerable weight.

CASE VII.—This is a gastric ulcer case, referred by Dr. H. Ulbrich of Detroit, who presents the following case history: "Mr. G., age 47 years; occupation, paint grinder, handles white lead. Father died at 73 or 74 of carcinoma of stomach (?). Mother died at 73 of pneumonia. *Past History.*—Smallpox at 12 years. Rheumatism in 1900 and in 1916. Lighter attacks in between times. *Present Illness*—Started two months ago with vomiting. Mucus aggravation morning on arising. wakens at night with dryness of mouth. Rolling in stomach ends up like a ball in hepatic region, with pains in right chest, followed by eructations, after which he feels relieved for five or ten minutes, and then the process repeats. Pain in the lumbar regions. Arises from chair with difficulty. Headaches—frontal. Vertigo. Malaise. Lost 5 lbs. that he knows of. Urination $\frac{4\ D.}{O\ N}$ Bowels, constipated. Sleep poor; appetite gone. Nauseated. Distress after eating. Eats bread and milk. Small amount of coffee—three cups a day and one cup of tea. Pain comes on from one to one and a half hours after meals, worse mornings than afternoons, and lasts until the following meal. Food relieves for one to one and a half hours. *Physical Examination.*—Teeth poor. Pyorrhea. Post-pharyngoceles. Enlarged turbinates, chronic rhinitis, abdomen-liver dullness at lower rib. Some pain in right iliac, slight over gall bladder. No tension of muscles, no tumor.

January 22, 1920.—Urine: Slightly acid. Sp. gr. 1030. Albumin and sugar negative. Temperature 98°. Pulse, 80. Bl. P. 128-78 sitting. Bl. P. 128-90 standing. Heart: Apex, fifth interspace inside nipple. Dullness ½ c.m. outside nipple. Heart not enlarged. Sounds normal, no murmurs. Lungs: Nothing abnormal found. Abdomen: Some tenderness, right duodenal region. Pressure below ensiform cartilage causes pain to gall-bladder region. No tension of muscles. Genito-Urinary: Normal, except for slight varicocele. Rectum: No hemorrhoids seen. Extremities: No varicosity. Differential Count: Poly. 65.3; small, 17.3; Large, 16; transi., 1.5. *X*-ray findings: February 1, 1920. The barium meal passes through the esophagus without note. There is a slight retardation at the cardiac end of the stomach. The barium readily settles to the fundus of the stomach, the greater curvature of which is lying on a level with the umbilicus. The barium readily enters the duodenum. There is no dilatation of the stomach. No niche or incisura is visualized. The pars pylorica shows a persistent spasm which does not interfere with the passage of the barium. The duodenal cap does not show the typical appearance, but is slightly flattened. However, no niche or incisura is visualized. The peristaltic action of the stomach appears normal. The duodenum is situated in the usual position and is movable, showing no adhesion around the duodenum. Palpation over the pars pylorica causes pain. The plates verify the deformity at the pyloric end, which is persistent in all the plates taken. The further examination of the intestines and colon do not show any deviation from the normal. Roentgen Conclusions: Pyloric ulcer or carcinoma, (beginning carcinoma), most likely an ulcer."

When patient presented himself for treatment he was not able to work and felt scarcely strong enough to come to the office. Treatments of 50 mgms. of tissue thrombin were given March 3, 10, 17, 21, 24, and April 5 and 12. The first four reactions consisted only of pain in epigastric region, with increased gastric symptoms for about 6 hours during the day following the treatment. But the temperature did not vary, running from 97° in the morning to 98° in the evening. The fifth treatment brought no response, and the patient was well enough to go to work, not having vomited and having had only mild gastric distress for a week. The treatments given April 5 and 12 brought on no reaction, and at the time the patient felt as well as he ever did, being able to eat anything on the table without any distress. He has had no hyperacidity, pain or vomiting since, and has gained 17 lbs. in weight.

This case demonstrates that in gastric ulcer focal pain and hyperreflexia are the only reactions to treatment, and that a febrile reaction is not attained in this condition. Contrasted with the preceding case, this fact is well brought out and the diagnostic value as well as the curative value of the treatment emphasized.

CASE VIII.—This case illustrates the reaction in a carcinoma of the breast, associated with Paget's disease.

Mrs. P., housewife, age 47. *Family History.*—Father died of old age, at 81 years. Mother died of old age at 79. One brother died of heart disease at the age of 55; another died of apoplexy at 42 years. One sister and three brothers are alive and well. One child, age 22, alive and well. *Past History*—Chickenpox before 10 years of age. One attack of rheumatism nine years ago and another two years ago, neither of which lasted more than a week. No other sickness until onset of present illness. Menstrual periods regular and not very painful. *Present Illness.*—In March, 1919, first noticed pain in the right arm, shoulder-blade and right breast, which grew worse, so that by June she could not use the right arm at housework. By this time she became rather weak and "inexpressably tired all the time," and the pain in right breast just behind nipple interfered with sleep. She became short of breath on slight exertion and coughed considerably. The tumor was first noticed in April, 1919, four weeks after the pain set in. It was about the size of a walnut, and she became cognizant of the fact that the nipple appeared fissured and smaller than the left one. She was examined by Dr. J. Davis in August and October, 1919, as well as by several general practitioners, who diagnosed the condition as carcinoma and recommended immediate radical amputation of the breast.

I first saw the patient on November 5, 1919, and found the right breast larger than the left, the nipple

fissured and retracted, and exuding some blood and a slight amount of thin pus. The upper right aspect of the nipple was eroded and the areola and surrounding area converted into a characteristic Paget's condition. Behind the nipple a very tender and hard mass about the size of an egg was found. Two other small masses, one along the outer edge of the pectoralis major muscle and one at the inner end of the third interspace of the same side, were both found to be tender and immovable. Only slightly enlarged glands could be palpated in the deeper axillary region. The left breast was normal. Her weight at this time was 157 lbs., temperature 97.4°. Wassermann negative. Blood, alkalinity, CO_2 combined, 84 c.c. per 100 c.c.

A treatment of 50 mgms. of tissue thrombin was given November 5, followed in 24 hours by a chill, fever of 102.4°, dyspnea, incessant dry cough, severe headache, smarting eyes and nausea, and a very severe burning pain in the areolar region and a severe aching pain in the tumor. This lasted five hours and eased up gradually until it disappeared. For the next few days there was less pain than she had before treatment. The second treatment was given November 9, followed by a similar reaction on the next day for four hours. After this treatment the Paget condition looked much less angry and the discharge had stopped. A third treatment was given November 14, and a similar reaction set in in 24 hours but was not as severe as the former two, and there was no dyspnea. The bleeding had stopped when she presented herself for a fourth treatment, and the Paget condition now looked like a mild eczema that was nearly healed. She still had a mass about the size of a walnut behind the nipple, but it was less painful and did not interfere with sleep, and the pain in the arm and shoulder had practically disappeared. Palpation could not locate another mass. After eleven more treatments with rather mild reactions, the pain, tenderness and mass had entirely disappeared, the nipple had gradually returned to its normal position, and the entire areolar region had become normal. A slight deficiency was left in the upper right corner of the nipple and the breast as a whole is noticeably smaller than the left breast.

I sent her to Dr. R. Wollenburg on March 5, 1920. He reported that he found her in perfect health, with normal breasts. I also sent her to Dr. James Davis January 25, May 5, and July 26, 1920, for examination. He reported not being able to find any suspicious tissue after thorough examination.

Patient has been given several treatments at intervals of four weeks without any reaction following, and has now remained tentatively cured six months. She has gained six pounds, and reports that she is not fatigable and can use her arm at washing cloths, etc., without any pain and as well as she ever could. Blood alkalinity, CO_2, combining power 57 c.c. per 100 c.c.

CASE IX.—The following case is presented to illustrate the type of response elicited in a rapidly growing squamous-cell carcinoma in a young patient.

Mrs. W., age 33, normal weight 130 lbs., three years ago. Referred by Dr. F. E. Thompson. *Family History.*—Father alive and well, age 75. Mother, age 68, alive and well. Mother's sister died of cancer of the stomach at the age of 68. Two sisters died in infancy, one of colera and one of dropsy. Another sister died of diphtheria when 5 years old. One brother died of diphtheria, age 8. *Past History.*—Measles, mumps, pertussis and diphtheria in childhood. Well until present illness. *Present Illness.*—Started in June, 1919, with severe pain in lower back and a urinary frequency of every 30 minutes, accompanied with severe pain on micturition, and severe, constant headache. Patient was "very tired and weak all of the time." Several times a day deep, cutting pains occurred in lower abdomen. Discharge was excessive, somewhat bloody, but not very odorous. She consulted Dr. F. E. Thompson and also Dr. Wm. Donald on October 1, 1919, who diagnosed the condition as carcinoma of the cervix. A specimen was removed by Dr. Donald for microscopic confirmation. The diagnosis returned was squamous-cell carcinoma of the cervix uteri.

On November 19, a vaginal hysterectomy was performed by Dr. F. E. Thompson. The tissue removed was examined microscopically and diagnosed squamous-cell carcinoma. For the first two weeks after operation, patient appeared to improve, but in the following two weeks this improvement gave place to a rapid decline. The rectum became so painful that the sitting posture was impossible. The very severe pain that developed in the abdomen increased, so as to cause reflex paralysis of the limbs and inability to either walk, turn over in bed, or reach for things. This was accompanied by intense pain in the hips and thighs, constipation and loss of appetite. The patient was examined by Dr. Thompson on December 20, as well as by myself, and found to have carcinomatous recurrence between the vagina and the rectum, in the rectum, and symptomatically in the region of lumbar and sacral plexes, and in the liver.

She presented herself for treatment December 21, 1919. She could not walk; weight 115 lbs. A treatment of 50 mgms. of tissue thrombin was given at 9 P. M., December 21, 1919. On the next day at 10 P. M., 25 hours after treatment, the patient awoke with fever of 104.3°; pulse, 120; intense headache, backache, grippy pains all over the body, and nausea all night until 10 A. M. next day. Within 3 hours after its onset the temperature rose to 105.2°, and did not fall below 104° until after 9 A. M. the next day. A drenching sweat followed the fever and the patient then felt much better than she had for the past four weeks. December 23, a second treatment of 25 mgms. was given. This was followed in 24 hours by a fever of 102°, lasting from 11 P. M. to 5 A. M. of the next day and accompanied by the other features of the former reaction, but not so severe. After the reaction subsided the patient could turn over or lie in bed on either side and was able to take a few steps. On the next day she could limp about, had a better appetite, and her bowels moved without so much pain. On December 28, 5 days after the second treatment, she walked ¼ mile without limping, and was without any pain whatever. Temperature 98.2°, pulse 80. On December 30, 1919, January 2, 6, 10, 12, and 27, 1920, she received additional treatments. The reactions gradually let up in severity after four of these treatments and then did not occur again.

She was examined by Dr. Thompson April 5, 1920, and no suspicious tissue could be found. She was likewise examined May 18 and July 1, and pronounced cured by Dr. Thompson (tentatively cured, of course). She was given a trial treatment July 16, 1920, but no reaction was elicited. The patient is perfectly well to date, her present weight being 149 lbs. She works hard all day without fatigue, pain, discharge, or any signs or symptoms of cancer.

DISCUSSION OF CASE HISTORIES.—*The Reaction.* Every carcinoma case presented, generally 24 hours after the treatment, developed a febrile reaction, accompanied by increased focal pain and hyperreflexia of the affected part. Moreover, a systemic intoxication is expressed in the grippy feeling accompanying the reaction. These phenomena are no doubt due to the swelling of the coagulated tissue and to oxidation of the absorbed products. That these products are to some extent toxic is illustrated in the case of Mrs. Z., who had severe reactions from the large doses given and who developed a temporary tetanoid condition.

I might cite briefly in this connection a case of very extensive carcinoma of the ovary. Mrs. W., referred in August, 1919, by Dr. Larson. This patient, from sheer exhaustion, was barely able to move about in bed, and after receiving three treatments died in a reaction from the intoxication of absorption of the killed cancer tissue. Autopsy showed that the large mass was entirely caseated and could be torn to bits without resistance. This toxic reaction has a diagnostic value, since it occurs constantly in cancer patients. I have not been able to obtain either a focal or a febrile reaction by injecting as much as 2,000 mgms. of the tissue thrombin in healthy men, or in noncancerous patients with gummata, tabes or tuberculosis.

Moreover the focal reaction is of value in determining the distribution of the cancer tissue. For instance, those cases of breast cancer with pulmonary involvement develop dyspnea and dry cough during the reaction, as in the case of Mrs. P. I may cite as an illustration of the possible severity of a focal reaction the case of Mrs. S., referred by Dr. J. H. Carstens in October, 1919. This patient weighed about 170 lbs. *X*-ray plates showed marked pulmonary involvement in both lungs and a dilatation of the heart, especially on the right side. In her right breast was a hard mass 9 c.m. long and irregularly 4 c.m. thick. The skin was movable above it. In the left axilla were a mass as large as a lemon and also several smaller masses. The left breast had been removed two years previously; the scar remaining appeared healthy.

This patient suffered quite severe dyspnea, the respiration running generally around 38, while the heart rate was variably 140. She was very cyanotic and the slightest exertion brought on intense dyspnea. Cough was incessant. The patient could not repeat more than two letters of the alphabet without taking breath. She was given six treatments, of 10 mg. each, weekly. The improvement in respiration was so marked that she could get up and walk about, only breathing twenty-eight times per minute. In the meantime the mass in the right breast disappeared, and the mass in the left axilla had diminished in size to that of a walnut. During the reaction periods she required constant stimulation, and even then the cough and dyspnea were almost unbearable. Her reaction temperature varied between 101° and 102°. After having improved so markedly, I risked a treatment of 50 mg., which proved to be too much for the patient, and she died in a reaction of cardiac failure. There was sufficient cancer left in the lungs, no doubt sufficiently swollen during the reaction, to obstruct the pulmonery circulation and cause failure of the right ventricle. An autopsy was not obtainable.

This illustrates that in very extreme cases the focal reaction also may be dangerous and that here the dosage must be guarded.

The gastric ulcer case showed no febrile reaction. We therefore now possess an additional means of characterizing cancer by the febrile reaction elicited by this treatment and, since this depends upon the chemical and physiological properties of the cancer tissue, it depends upon the intrinsic essential structure of the cancer and is therefore more valuable as a diagnostic feature than the microscopic characteristics. Furthermore, a good thermometer is the only instrument needed to estimate the fever and the personal equation for error cannot be so great as that to which the pathologist is subject.

The Results of Treatment.—These are, as illustrated by the cases presented, disappearance of the tumor and its attendant cachexia, return to normal of the blood chemistry—the alkalinity, for example; increase in the blood count and hemoglobin content—a doubling of the blood count in four weeks, for instance; increase in weight to normal or above normal, as in the case of Mrs. W.—often an increase of 40 lbs., cited in Cases I and IV; complete disappearance of pain and soreness and return of function, as in the case of Mrs. Z., where a previous achlorhydria gave place to a 0.9 per cent. HCl content in the gastric juice, incident, of course, to the return of the blood alkalinity to normal. The rapid recuperation of the patient after the carcinoma has disappeared, and the loss of easy fatigability, as demonstrated by these cases, are also significant.

The Sequelæ.—The sequelæ are also physiological. In a region as the breast of Mrs. P. (Case VIII), a deficiency exists in place of the cancer tissue. In a region where there is a necessity for replacement of the cancerous area by scar tissue this takes place, as in the case of Mrs. B. (Case I), where a large vesico-vaginal fistula was entirely replaced by scar tissue and the deficiency made good.

That the tissue thrombin itself is not injurious to the patient is illustrated in the cases presented by failure to obtain a reaction after the cancer tissue has disappeared, by the steady gain in weight during treatment and by the increase in the blood count and in the hemoglobin content during and after treatment, and by the normal noncoagulable nitrogen content of the blood after treatment, which indicates that no injury has been done to the kidney.

The isolation of the thrombin free from products that are injurious and that promote cancer growth is a matter of great difficulty and only after over three years of constant experiment have I succeeded in working out the only two possible methods that can yield a useful product.

The chemistry of the thrombin, its isolation and certain synthetic work will be reported in some chemical journal. I owe my deepest gratitude to the clinicians who have cooperated with me so kindly in this work.

OUTLET PELVIMETRY.

BY GEORGE H. PIERCE, A.B., M.D.,

NEW YORK.

INSTRUCTOR IN OBSTETRICS NEW YORK POST GRADUATE MEDICAL SCHOOL AND HOSPITAL; OBSTETRICIAN, HARLEM HOSPITAL OUT PATIENT DEPARTMENT; ATTENDING OBSTETRICIAN, COLUMBUS HOSPITAL.

OUTLET pelvic mensuration is so important and yet is so little understood and practiced (in general) that its principles cannot be too often brought before the medical profession. It concerns every physician who attends a woman in childbirth, to know the size of the pelvis; both its "inlet" and its "outlet."

In 1915 I presented this subject, together with the description of a *pelvimeter*, for measuring the transverse, posterior sagittal, anterior sagittal, and anteroposterior diameters of the pelvic outlet; and the height of the symphysis pubis. During the five years that have elapsed the demands of the Government lessened the services of instrument makers for individuals; and as a consequence, the manufacture of the little instrument was stopped after a few had been produced. Meanwhile we have been

putting it to practical test in a large antepartum clinic and its general principles have been found to be as satisfactory as at first anticipated. Two changes, however, have been made in the mechanism: one, by which it will now measure a transverse of any length from 6 cm. to 11 cm.; and the other change, whereby the thumbscrews have been eliminated; the caps and transverse rod now working by screw thread action; making the instrument even simpler than when first constructed.

Description of the Pelvic "Outlet."—By the *outlet* is meant the bony outlet, which comprises the *two planes* which may be considered practically as one area, bounded by the pubic arch and the immovable *anterior* tip of the sacrum. When this area is too small, a child's head which normally fits under the pubic arch cannot pass uninjured. It is here that the forceps is so often used with destructive effects to both child and mother, owing to the narrowness of the pubic arch. If knowledge of the limited area is known beforehand, as it can be known by measuring it antepartum, or even in the early part of labor, other means of delivery may be substituted. The attempt to drag a head through an impossible pelvis is not warranted. We may not be able to measure accurately the child's head, but we can tell by measuring when a pelvis is too small for *any* head to pass.

The Pelvic Diameters.—The transverse diameter of the pelvic outlet is the distance between the lowest innermost margins of the tuberosities of the ischium; in the living, normally 10.5 cm.

The distance from the transverse to the *anterior* tip of the sacrum is the *posterior-sagittal diameter;* the distance in a straight line from the center of the transverse to the *sub-pubic* arch is the *anterior-sagittal* diameter; and from sub-pubic arch to the *anterior* tip of the sacrum is the *antero-posterior* diameter of the pelvic outlet. Geometrically these lines form a triangle.

In *funnel pelves* the *available outlet* is practically between the transverse and the anterior tip of the sacrum:

Transverse 8	cm.	Posterior-sagittal must be at least	7.5 cm.
Transverse 7	cm.	Posterior-sagittal must be at least	8 cm.
Transverse 6.5	cm.	Posterior-sagittal must be at least	8.5 cm.
Transverse 6	cm.	Posterior-sagittal must be at least	9 cm.
Transverse 5.5	cm.	Posterior-sagittal must be at least	10 cm.

The head of average size will pass the outlet if the transverse is 8 cm. or above and the posterior sagittal 7.5 cm., *the normal length.*

In pelves of normal size the subpubic arch is wide enough for the head to pass immediately beneath it; but with a narrow pubic arch, as shown in the table, the head must pass, if at all, below the arch at a distance from it down the pubic rami, varying according to the degree of narrowing; and in order to do this, the tip of the sacrum must be located farther back than it is in its normal position. If sufficient compensation exists, it forms a *new available outlet;* the *transverse,* tubero-ischial diameter being substituted for the pubic arch and the *posterior sagittal* diameter being substituted for the anatomical anteroposterior.

To Measure the Pelvic Outlet Diameters.—The pelvic outlet diameters are the *tubero-ischial* or *transverse,* the *posterior sagittal* and the *antero-posterior.* The transverse measurement is made between the lowest inner margins of the tuberosities of the ischium. The anteroposterior is *measured* from the subpubic arch within the vagina, to the tip of the sacrum *posteriorly* and deducting 1 cm. to allow for the thickness of the sacral tip. The *posterior sagittal* diameter cannot be measured directly, but may be approximated by carrying the tip of the pelvimeter backward over the tissues to the tip of the sacrum posteriorly and subtracting 1 cm. to allow for the thickness of the tip. It is impossible to measure this diameter without having a fixed transverse base line. *It was for the purpose of providing this base, adaptable* to the *varying widths* of the *transverse, together with a means in a single instrument* for *measuring from this base to the sacral tip posteriorly, that this pelvimeter was devised.*

Pelvic mensuration is not only practical, but *imperative!* Measurement of the pelvic outlet diameters should be included in every antepartum examination. This little instrument measures a transverse of from 6 cm. to 11 cm., and the other diameters as required. Figures are placed conspicuously at 8 cm. on the transverse rod and at 8.5 cm. on the curved rod to fix the attention upon these points, because they represent frequent limits of availability whereby the head may pass.

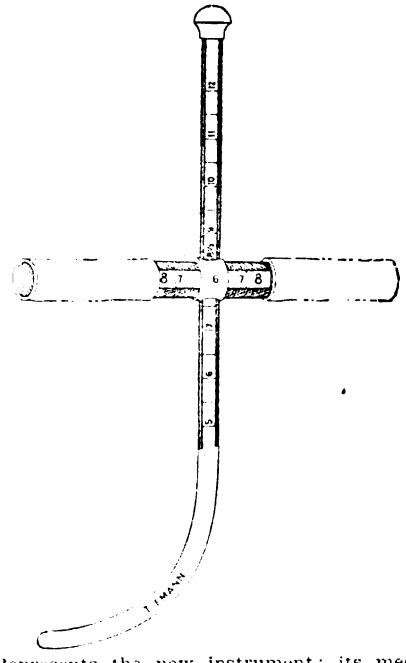

FIG. 1.—Represents the new instrument: its mechanism is by screw threads; set for the first tryout. (8 x 8½).

The mechanism of the instrument is by a screw thread action. The caps screw out and in, and the curved rod screws up and down through the transverse rod. The scale on the rods is marked at ½ cm. intervals.

To measure 7, 8, 9, 10 cm., etc., on the transverse rod, the screw caps are to be placed at corresponding figures on each side of the central rod to indicate the increase or decrease of 1 cm.

The normal length of the transverse, tubero-ischial diameter as measured in the living subject, *i.e.* over the tissues, is 10.5 cm.; and the normal length of the posterior sagittal diameter is 7.5 cm. Spontaneous birth of the head is still possible with the tubero-ischial diameter shortened to 8 cm.; the posterior sagittal remaining 7.5. if the tubero-ischial diameter is shorter than 8 cm. the head will

not pass unless the posteriol sagittal is lengthened.

If the tubero-ischial is 8.0 cm. the posterior sagittal must be at least 7.5 cm.
If the tubero-ischial 7.0 cm. the posterior sagittal must be at least 8.0 cm.
If the tubero-ischial 6.5 cm. the posterior sagittal must be at least 8.5 cm.
If the tubero-ischial 6.0 cm. the posterior sagittal must be at least 9.0 cm.
If the tubero-ischial 5.5 cm. the posterior sagittal must be at least 10.0 cm. —(Williams).

At the distance of 8.5 cm. from the tip of the curved rod on the pelvimeter in a straight line the figures 8½ are placed; because the measurement from this point on the cross bar to the tip of the sacrum externally, less 1 cm., represents the normal

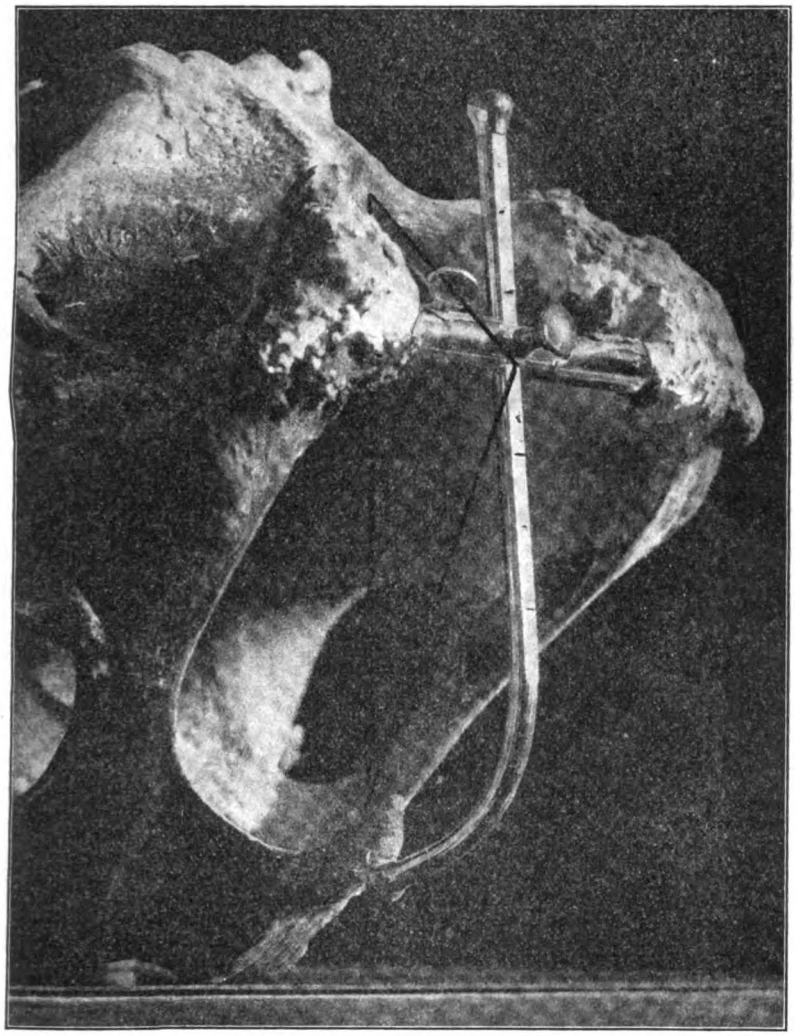

Fig. 2.—Represents the pelvimeter presented in 1915, measuring a transverse of 5.5 cm., and posterior sagittal of 10 cm.; connecting lines form a triangle representing the outlet diameters. The lower margin of the transverse bar of the instrument rests at the transverse of the outlet.

length of the posterior sagittal diameter 7.5 cm. (the measurement to the tip of the sacrum *internally*). *The posterior extremity of the true sagittal diameter is at the tip of the sacrum on its anterior surface, internally; so that* 1 *cm. must always be subtracted from the distance actually measured externally.* Other figures up to 13.5 cm. are similarly placed on the rod at 1 cm. and ½cm. intervals. *They indicate the other distances to which the posterior sagittal diameter must be lengthened to compensate for the variations in shortening of the tubero-ischial diameter.* Thus, for example:

If the reading for the
Posterior sagittal is 8.5 cm. subtracting 1 cm. equals 7.5 cm.
Posterior sagittal is 9.0 cm. subtracting 1 cm. equals 8.0 cm.
Posterior sagittal is 9.5 cm. subtracting 1 cm. equals 8.5 cm.
Posterior sagittal is 10.0 cm. subtracting 1 cm. equals 9.0 cm.
Posterior sagittal is 11.0 cm. subtracting 1 cm. equals 10.0 cm.

Use of the Pelvimeter.—A good light and posture of the patient are essential, especially if the patient is stout and the tuberosities thickly covered. One should not feel that he must hurry in defining the landmarks. A good method of procedure is to place the patient in the extended lithotomy posture on a table, with the hips well over the edge, so that the tip of the sacrum may be palpated. It is well to have the sacrum rest on a pad to protect the patient from the edge of the table. The lithotomy posture may be maintained with leg holders; or by having the feet with slippers on, rest against the top of the backs of two chairs, which are higher than the table; one chair being placed for the right and one for the left foot. This posture brings the tuberosities into prominence and prevents the *tendency to measure* the transverse diameter at a *point higher* than the tips of the tuberosities which would give a *false measurement,* viz., *one too narrow.* It is more convenient if the physician is seated. The instrument measures any distance transversely, from 11 cm. down to 6 cm. The pubic arch may be palpated from above downward with the thumbs. When the width is estimated in this manner or with the knuckles of the hand bent at the second phalangeal joint pressed between the tuberosities; the caps of the transverse bar are to be adjusted and their ends pushed up with the thumbs and trial made *to see if the distance between the tips of the tuberosities is as great as the bar drawn out.* If it is not, the instrument is taken off, and the caps set, and trial again made. (This is easier than attempting to measure the distance directly by holding the ends of the caps between the thumb and fingers and palpating and moving the caps at the same time.)

The bar now measuring the transverse diameter is held by the operator in position, and the *posterior sagittal* diameter is next measured by bringing the tip of the curved rod around to the tip of the sacrum, *and subtracting* 1 *cm.* from the distance measured. For trial the *upper* margin of the transverse rod may be fixed on the perpendicular rod at the 8.5 cm. mark.

To locate the tip of the sacrum.—If not easily felt externally, palpate the coccyx, by introducing the index-finger of one hand into the vagina; and making counter-palpation with one or two fingers of the other hand on the outside. The rectum should be empty. The coccyx is composed of four bones, which in my experience are partially movable, especially in young subjects.

Again, the coccyx is about 1¼ *in. long* (3 *cm.*);

so that, bearing in mind its usual length, its upper termination will be approximately 1¼ in. above its tip.

To Measure the Anterior Sagittal Diameter.—Place the tip of the short curve of the curved rod against the sub-pubic arch, within the vagina; and bring the transverse bar to the level of the tuberoischial line. Normal length, 5 to 6 cm. Measurement may also be made from the transverse rod upward to the sub-pubic arch.

To Measure the Anteroposterior Diameter of the Pelvic Outlet.—Place the tip of the short curve of the curved rod against the outside tip of the sacrum and measure in a straight line to the symphysis pubis within the vagina. Subtract 1 cm.

Essentials.—1. Posture: Place the patient in the dorsal or lithotomy posture with the tip of the

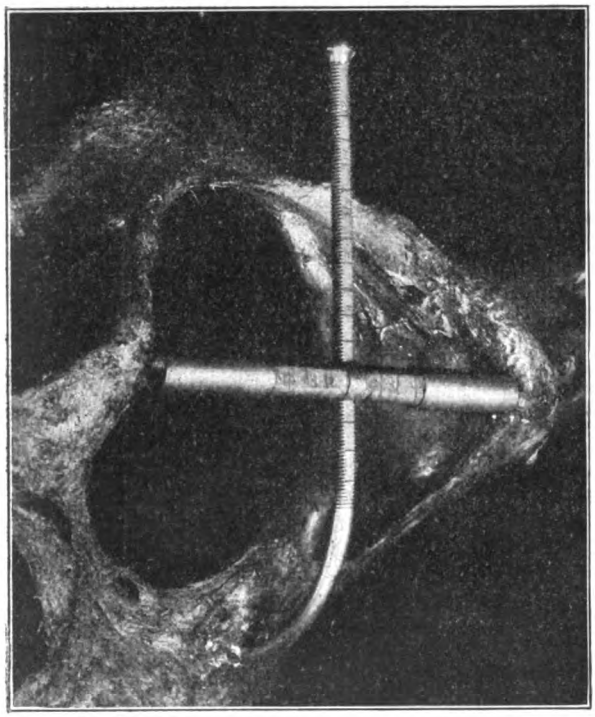

FIG. 3.—Represents the *new* pelvimeter measuring a transverse diameter of 9.5 cm. and a posterior sagittal diameter of 6¼ cm. The upper margin of the transverse bar of this instrument rests at the transverse of the outlet; being more satisfactory to push the upper margin of the ends up against the tuberosities when measuring. The respective outlets in these two pelves show different conditions. The first, a very narrow transverse; but with a compensatory sufficiently long posterior sagittal to admit the passage of the head (see table); the second pelvis has a sufficiently wide transverse outlet; but the posterior sagittal is so short that no head could pass.

sacrum well over the edge of the table. 2. Palpate the ischial rami downward with the thumbs to the *lowest innermost limits of the tuberosities* of the ischium at about the *level of the anus*, to estimate the transverse. 3. Note this distance with the eye and adjust the screw caps on the transverse rod to correspond with the distance estimated; then with the thumbs press the ends of the rod against the tuberosities at their lowest inner margins; making the adjustment until the distance is measured. 4. Having measured the transverse, lay the instrument aside for a moment and palpate the coccyx to locate the *tip of the sacrum.* Keep a finger here or place a small strip of adhesive plaster. Replace the *upper* margin of the transverse bar at the tuberoischial level and see if the tip of the perpendicular curved rod, *with the transverse fixed at the 8½ cm.* mark on the perpendicular rod, will swing around to the tip of the sacrum; if so, the length of the posterior sagittal diameter will be 7.5 cm., the normal length. If it does not reach this point, screw the rod down or up until it does reach it, and note its length. 5. Do not forget to measure the occipitofrontal diameter of the *child's head* through the abdominal wall (normal 11.50 to 11.75 cm.) and subtract 2 cm., which will give approximately the bi-parietal diameter (normal 9.25 to 9.50 cm.).

To simplify the idea of subtracting 1 *cm.* in measuring the posterior sagittal diameter, the *actual measurement* to the outside tip of the sacrum may be *substituted* as expressed in the table given for lengths of the transverse and posterior sagittal; which must be present in order that the head may come through the outlet; so that the table for *immediate computation without subtracting* would read as follows:

FOR AVAILABLE OUTLET—BY DIRECT MEASUREMENT:

Transverse 8 cm. distance to *outside* tip of sacrum must be 8.5 cm.
Transverse 7 cm. distance to *outside* tip of sacrum must be 9 cm.
Transverse 6.5 cm. distance to *outside* tip of sacrum must be 9.5 cm.
Transverse 6 cm. distance to *outside* tip of sacrum must be 10 cm.
Transverse 5.5 cm. distance to *outside* tip of sacrum must be 11 cm.

This means that if:

Transverse is 8 *postr. sagittal* would be 8.5 — 1 = 7.5 cm.
Transverse is 7 *postr. sagittal* would be 9 — 1 = 8 cm.
Transverse is 6.5 *postr. sagittal* would be 9.5 — 1 = 8.5 cm.
Transverse is 6.6 *postr. sagittal* would be 10 — 1 = 9 cm.
Transverse is 5.5 *postr. sagittal* would be 11 — 1 = 10 cm.

TRAUMATIC GENU RECURVATUM:

REPORT OF A CASE IN AN ADULT.

BY S. KLEINBERG, M.D.,

NEW YORK.

MRS. O., 36 years old, slipped while walking and injured her left hip. On account of a very severe nervous breakdown which followed immediately, treatment of the injured joint was suspended. After about three months a long brace was applied for the support and protection of the hip. We have very few details as to the exact diagnosis or progress of the hip condition, but the history very distinctly indicates that during the wearing of the brace, the knee was permitted to sag backward so that a recurvature was established. The patient stated also very positively that the inner bar of the brace continually pressed upon and irritated her knee. When this brace was removed another one was applied extending from the groin to the foot. This latter brace consisted of two upright bars with a continuous leather cuff from the middle of the thigh to the ankle, but it did not hold the knee straight, nor prevent it from bending backward.

When the patient first consulted me she wore this latter brace and walked with the aid of crutches. Without the crutches she could take a few steps, but only with great difficulty. The left lower limb was markedly deformed at the knee, the deformity consisting of a knock-knee condition and hyperextension to about 20 degrees beyond the straight line. The knee was immobile. The deformity appeared as shown in photograph (Fig. 1). The great trochanter was very prominent, elevated above the normal level, and the hip was ankylosed with the thigh in about 10 degrees of adduction. The *x*-ray pictures (Figs. 3 and 4) showed outward subluxation of the tibia producing the knock-knee, hyperextension of the knee and fusion of the femur and tibia through a curved bar of bone extending between and uniting the internal condyle of the femur and the inner aspect of the tuberosity of

the tibia. The articular surfaces of the femoral condyles and the tuberosity of the tibia were apparently undisturbed. The *x*-ray of the hip showed partial destruction of the head of the femur and bony fusion of the remainder of the head and the acetabulum.

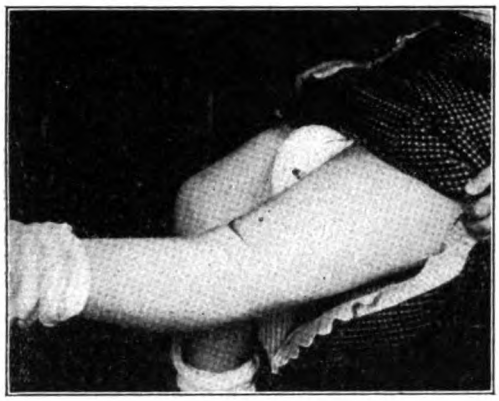

FIG. 1.—Mrs. O., before operation.

The treatment indicated was evident. No correction of the deformity could be hoped for without removal of the osseous bridge uniting the femur and tibia. Accordingly, the patient was operated upon. A vertical incision was made over the inner side of the knee and a very dense mass of bone was found uniting the femur and tibia. This bone was part of the capsule of the joint, and did not invade any of the subcutaneous tissue. It replaced the inner part of the joint capsule and the internal lateral ligament. The bone was chiseled away at the joint line, and then the joint could be moved through an arc of about 30 degrees. The limb was then manipulated and the deformity partly corrected. The contracture of the soft tissues about the knee was so great that complete correction of the deformity was impossible. However, as shown in Fig. 4 the extraneous bone was removed, the knock-knee partially corrected, the recurvature almost completely corrected, and, as seen in Fig. 2, the cosmetic result is very good.

FIG. 2.—Mrs. O., after operation.

It had been our hope, inasmuch as we obtained some motion in the knee at the time of operation, that this motion could be increased with prolonged after-treatment. However, observation showed that while we could and did maintain the correction, the knee was so sensitive that manipulation was impossible, and finally the ankylosis recurred, although it is probably fibrous.

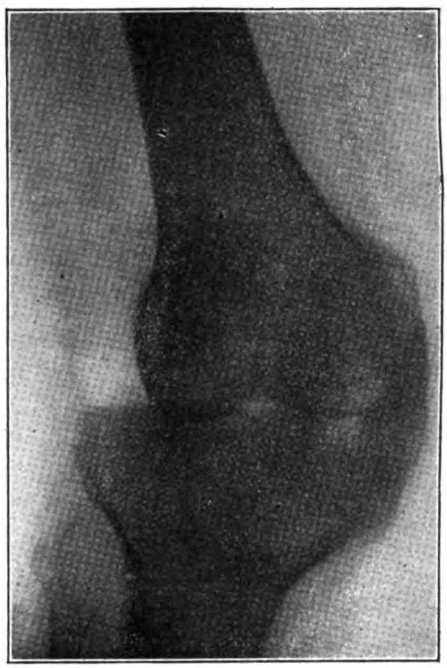

FIG. 3.—The knee-joint before operation.

This case is of special interest, first, because the deformity, a combination of genu recurvatum and genu valgum, is unusual in an adult, and secondly, the deformity resulted, as far as we could ascertain, from an improperly fitting brace. The brace had no provision for support of the knee, so that the knee sagged backward until finally a recurvature

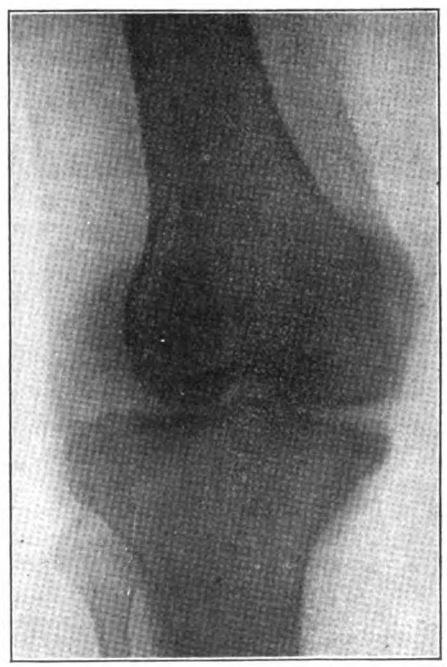

FIG. 4.—The knee-joint after operation.

was established. In addition the inner bar of the brace pressed against the knee, and by its irritation initiated a process of ossification which resulted in ankylosis.

In our daily experience with leg splints—either braces or plaster-of-Paris bandages—we have abundant proof that inefficient support of the knee, especially when support of the back of the knee is lacking, may result in a recurvature. We know, for instance, that in applying plaster or other splints for hip, thigh, knee or leg condition, the knee should be held slightly flexed, unless we are attempting to correct a flexion of the knee itself. Otherwise the knee will become relaxed and bent backward.

We do not, however, see ankylosis of a knee from splinting in cases where there was no inflammation or injury of the knee before the splint was applied. The localized ossification in this case is unusual, and we believe was the result of pressure irritation. It is also interesting to note that the ossification affected the inner part of the capsule of the joint and internal lateral ligament, but none of the other structures. It is, of course, possible that infection played some part in the ossification of the capsule of the knee joint. This is, however, unlikely as there is no history of a localized abscess or any inflammatory process on the inner side of the knee. Furthermore, the knee joint proper is free from adhesions, erosin of the articular cartilage or other evidence of infection or inflammation. The process in this case seems similar to that of ossifying myositis following a trauma.

The lesson emphasized by this case is that braces must fit accurately and should not produce continued and excessive localized pressure. Also that splints should support joints in a normal or neutral position and not in an attitude of deformity.

RECOVERY OF A NEEDLE FROM TENDON OF FLEXOR LONGUS HALLUCIS.*

By W. HOWARD BARBER, M.D.,

NEW YORK.

THE patient, E. G., a young woman 25 years of age, gives a history of having driven a needle into the heel of the left foot while bathing ten years ago. The exacerbation of pain during the past few days on walking led her to believe she might have injured her foot again. Physical signs are negative excepting for tenderness over the left plantar arch. Stereoscopic and other x-rays represented the needle buried in the plantar fascia and lying parallel to the first metatarsal bone. An incision was made in line with the neelle, the foreign body was recovered, and the wound was closed, all within five minutes. The operation revealed a rusted needle 3 cm. long, impacted within the tendon of the flexor longus hallucis muscle and underlying the shaft of the first metatarsal bone. The stiffness of the tendon, as though calcified, drew attention to the possibility of the foreign body being within it. The tendon was split before the needle was exposed sufficiently to withdraw it. The instructive factors in this experience are:

1. The progression of the needle within the tendinous fibers of the long flexor of the great toe.
2. The sudden appearance of pain ten years after entry.

Roentgenogram of E. G. with tendon of flexor longus hallucis sketched in to illustrate the site of the needle lying completely imbedded within the tendon ten years after entry into the patient's heel. (Case referred by Dr. J. Kelly of Scranton.)

3. The value of stereoscopic pictures for preoperative study and the importance of anteroposterior and lateral views for localization at the time of operation.
4. The importance of searching aponeuroses and tendons in the long-standing cases of foreign bodies in the extremities.

A SPINAL SIGN IN GASTRIC CRISES OF TABES;

THE POINT OF ORIGIN OF SUCH ATTACKS, AND THEIR TREATMENT.

By WILLIAM BROWNING, M.D.,

BROOKLYN, N. Y.

OF the various crises and episodes that occur in the course of tabes the gastric form is accounted the most frequent. And all the severer seizures of this kind are so distressing, exhausting, and sometimes even dangerous as to demand careful attention. The suddenness of onset and urgent character of these attacks do not favor careful observation. At least the customary descriptions mention little more than the emesis, prostration, and pain.

There is one sign in connection with these attacks, that has either never been noted or has not found general recognition. If observed at all it has doubtless been passed over as too insignificant for mention, but for many years the writer has found it useful as a diagnostic aid, and of recent years also as a therapeutic indication.

It is a relatively easy matter to elicit the sign, and it can be briefly described. It consists of a

point or small area of tenderness just to the left of the spinal column, corresponding to the fifth dorsal interspace or one at about that level. It is always to be found on the same side as the stomach. It may extend to more than one space, though usually most marked at a definite level. It rarely involves the other side, and then only in minor degree; I have seen but one such case.

The location relative to the spinal column is similar to that in so-called spinal irritation; but is distinguished by its unilateral character. A couple of slow searching strokes along the side of the spinal column by the tips of the thumbs or even of the fingers soon settles the question. An evident wince on the part of the patient or an expression of pain shows when the tender spot is reached.

Because a tabetic has a little nausea or gastralgia is not full proof of a crisis. In typical cases of this kind the sign appears to be regularly present for a time at least. Whether it precedes the onset of a crisis cannot be stated, but it has always been found as soon as a crisis case was examined.

Within a few days of the subsidence of the vomiting and concomitant distress this point of special tenderness rather rapidly subsides. And even towards the end of a prolonged attack the tenderness may become less marked. It is the more in evidence, as the tabetic is often relatively analgesic.

Point of Origin of these Attacks.—It is relevant to ask what is the point of origin of gastric crises? Although the systemic or luetic condition is the underlying etiologic factor, the immediate cause is more likely some intermediary process.

Whether the vomiting is of central origin, cerebral in type, a view largely held by Germans, or is due (Mills and others) to disease of the vagus, or is analogous to the pain and other crises of tabes and hence perhaps radicular in origin, does not seem to be determined.

Clinically there are several reasons for considering the "central" theory inadequate: (*a*) The initial symptom in some attacks is severe pain at the spine, preceding any evidence of disturbed gastric function, and in most cases there is at least attendant pain of spinal type, indicating that to be the primary or starting point. (*b*) Often these crises are accompanied by the occurrence or increase of pain elsewhere in the body. This suggests a flushing of the system with toxins or influences, and not merely a local process. And similarly in pain-crises elsewhere about the body, there is often evidence of a more general influence. (*c*) If these attacks are analogous (as is claimed and as seems plausible) to the pain crises of tabes, then they must be due to radicular or at any rate extracranial cause. (*d*) Furthermore, if this were a sequel, it might be expected to develop in other cases of persistent vomiting, whereas in fact it has so far proven to be a distinguishing mark. (*e*) The clinical facts given in this paper speak in the same sense.

While the material at hand may not give a full explanation of the way the vomiting is brought about, this much can be said,—that the evidence is sufficient not only to cast doubt on the completeness of the old or "central" theory of its origin, but to raise a question if it is applicable at all. It is another of those instances where the physiological and the clinical do not at first sight jibe. Physiologically the "central" interpretation may seem both necessary and sufficient. But no explanation is satisfactory until it accounts fully for the clinical facts.

This may parallel the idea, when emetics were first used hypodermically, that they acted centrally. Later this had to be modified somewhat when it was found that the agent had been excreted by the stomach.

As a corresponding herpes does not or not often attend a gastric crisis, and as the spinal tenderness so soon subsides, we cannot presume the existence of a full-fledged neuritis.

As irritative processes about the stomach and regions adjacent to the tender spot beside the spine may induce emesis, it is possible that such a result is produced along ordinary functional lines.

A convenient view is that both results are sequels of a widespread systemic influence (chemical, toxic, infective, nervous, or what not), including the spinal involvement as an integral part of the crisis complex.

The most certain conclusion is that these attacks are not in any strict sense "central" in origin, as has heretofore been so largely assumed.

Treatment of Gastric Crises.—Our common works on neurology give little or nothing regarding the treatment of these seizures. Pain, anorexia, and distress may terrorize the patient. Many have been subjected to operations in good part unnecessary. Occasionally prostration suggestive of a moribund state lasts for days, with but gradual recovery. Together then such cases make a record of suffering so severe and often recurrent as to warrant common sympathy and emphasize the need of something better than haphazard therapy.

The almost invariable way is to have prompt recourse to morphine or its congeners. But while this may numb the pain it greatly aggravates the nausea, upsets the digestion still more, and tends to prolong the attack. These patients also but too easily acquire a habit for such drugs. Some plan consequently is demanded that if possible does away with the use of opiates and anyway reduces their use to a minimum.

In fact Ostnakow (in Russian 1906; *v. Neurlgo. Centbl.* 1909, p. 14-17), after stating that the immediate cause of these crises had not been worked out, recognizes a toxic origin, and gives good reasons for attributing the development of gastric crises, in large part and sometimes wholly, to the use of morphine or other sedative.

As comparable crises have been reported in Graves' disease, in syringomyelia, and perhaps in other conditions, it is possible that the present plan is not then as applicable. In the tabetic form there are two general lines of attack that have proved useful:

(*a*) In the first place the irritation, presumably at the nerve root or ganglion, needs consideration. For even if the tenderness be but a sequel, some direct connection is evident, and a reverse influence is quite possible. Some form of counterirritation locally over the tender spot can be readily applied. For this doubtless any one of various favorite methods can be adapted to good purpose. The writer happens to be in the habit, for this particular purpose, of having blue ointment or else the 25 per cent

oleate of mercury rubbed in along the region of the tender spot. A half drachm or less suffices, and this can be repeated once a day as required.

It may be in part the massage and in part the mild skin-irritation, or some absorptive effect or some remoter action that does the most good. It is at least a rational method, and seems to be of material aid in limiting the crisis.

In other painful attacks in tabetics it is sometimes possible to find a tender point corresponding apparently to the exit of the respective nerve from the spinal column. In such cases also a similar plan over the tender spot beside the spine can be profitably adopted.

Where the pain is severe or an immediate impression is imperative, recourse can be had to the therapeutic *x*-ray locally at the region of the sensitive root. This has long been used in a similar way for other tabetic pains. Otherwise, as far as practicable, it is well to begin treatment with counter-irritation, and follow with the *x*-ray if necessary.

(*b*) Internal Remedies: Treatment by the stomach may seem hopeless. Though apparently favorable results have been obtained often enough to be fairly conclusive, the word "seem" is used because a seizure may cease spontaneously. Liquids of any bulk are not advisable. But some things will remain long enough in the stomach or leave sufficient traces of their substance to exert a favorable influence.

For this purpose a useful combination is a powder containing gr. 1-100 each of calomel, brucia, and powdered ipecac. This is given every half hour or oftener for brief periods, according to the urgency of the case or the degree with which it is rejected by the stomach. Sometimes the amounts in the above dose are doubled for a short time. It is usually gratifying to find soon that the attack is lessening or has stopped. Then the agent can be diminished or dropped.

In other forms of vomiting, notably that of alcoholism, similar combinations are invaluable. Hence it is not necessary to assume any specific influence of these remedies in the crisis cases.

Where the attack is less acute and there is prospect that a few drops of fluid can be retained for a time at least, or in cases where there is hypochlorhydria, it is sometimes well to give, instead of the above powder, a drop of compound tincture of iodine in a teaspoonful of water with the same frequency.

The results in cases that have been followed for considerable periods give the impression that this general method of treatment tends also to prevent repetition of attacks. Recurrences are, however, so lacking in rule, that even much experience may not be conclusive on this point. And if morphine is really a causative agent, its exclusion must have a preventive influence.

In any case a radical revision of the usual methods of handling these outbreaks is in order.

54 LEFFERTS PLACE.

New Signs of Sciatica.—Rimbaud directs attention to retromalleolar effacement and the reflexes of plantar percussion as signs of sciatica or lesions of the sciatic nerve. Retromalleolar effacement occurred in 70 per cent. of surgical lesions of the sciatic and in 25 per cent. of medical sciatica cases observed by Rimbaud. Disappearance of the reflex flexion of the foot is an early sign of a sciatic lesion.

ACQUIRED SYPHILIS IN THE AGED

BY BURTON PETER THOM, M.D.,

NEW YORK.

VISITING SYPHILOLOGIST TO THE HOSPITALS OF THE DEPARTMENT OF CORRECTION, BLACKWELL'S ISLAND.

PRIMARY syphilis in the aged is comparatively rare. It is impossible to estimate its incidence because of the absolute lack of statistics. According to Sigmund, extragenital chancres are more frequently encountered in the aged than in those younger in years. From my own experience I can neither confirm nor deny this. I am quite certain, however, that extragenital chancres are not so frequent in the aged as they are in children. Strange as it may seem when we consider the importance of the subject, there is scarcely any mention of this aspect of the disease in American or English literature. It would seem that it has been studied only by the Germans and the French, especially the latter. It is from the writings of Continental authors, therefore, that most, if not all, of our knowledge is derived. A brief résumé of their observations in English appeals to me as a contribution worthy of regard to English speaking syphilologists and practitioners of general medicine.

Syphilis acquired in advanced life presents certain differences in its evolution and its impress on the organism from syphilis acquired in the more virile period of the life cycle. When contracted in old age syphilis is on the whole more severe than when contracted earlier in life. This is the consensus of opinion of all syphilologists. The only exceptions that I know of are Sigmund and Lagneau. Sigmund during thirty years collected one hundred and eighteen cases, of which eighty-seven were males and thirty-one were females. His analysis of these cases led him to conclude that the disease, when acquired in old age as compared to when acquired in youth or middle age, was milder and responded more readily to treatment. Lagneau, writing in opposition to Ricord, asserted that "The rigidity of the vessels walls and the diminished vitality of the tissues are an impediment to the quick development of the symptoms. For this reason venereal disease in the aged does not develop as rapidly as in younger persons." I am utterly at variance with their conclusions. Dulac from a study of forty cases noted that senility aggravated the disease and that its manifestations were more pronounced and more rebellious to treatment. Regoby observed that the course of syphilis in the aged was more severe than when occurring in younger individuals. Bumstead and Taylor in their work on syphilis published in 1883 remarked: "When contracted in old age, syphilis is frequently a very serious disease. . . . The tertiary lesions are prone to appear early, and visceral complications and nervous affections are frequent." Mendel reports three cases occurring in individuals of advanced age in whom hemiplegia developed shortly after the appearance of the initial lesion. Although unusual, this can and does occur in younger patients as well. Engelsted, Braus, Gjor, and Fournier have reported cerebral involvement within a few weeks of the appearance of the chancre. Udo J. Wile reports four cases of syphilis in patients sixty, sixty-two, sixty-four, and seventy-nine years of age.

All of these were genital infections following coitus. In two iritis and iridocyclitis developed shortly after the appearance of the initial lesion.

The great Ricord emphasized the severity of syphilis in the aged when he wrote: "Syphilis does not love the old; it plays them a hundred tricks which it does not try on the young." Fournier expressed the same opinion in the following: "Syphilis kills old persons and children in a way not to be found in regard to adults." Gailleton states that syphilis contracted after sixty years of age is nearly always fatal, because of rapidly developing visceral lesions or from the profound cachexia which the disease induces. The same opinion is maintained by Lebard, assistant to Gaucher at the *Hôpital de St. Antoine.*

From the array of authorities I have quoted the reader cannot but appreciate that syphilis acquired in senescence is much more active and formidable than it is in the earlier years of life. Let us now consider the course and behavior of the disease when it attacks in the evening rather than in the morning or noonday of life.

The period of incubation of the chancre when acquired in youth or middle age averages from three weeks to a month. It may be shorter; it may be longer; but such is the exception. In old age the period of incubation is long—five to seven weeks. In younger adults, unless cachectic from diabetes, alcoholism or tuberculosis, the chancre is almost invariably a benign, even insignificant lesion. Not infrequently the patient is unaware of its existence, and in after years denies with truth any knowledge of such a sore. In passing, I wish to say, that this happens more often than is usually supposed. In the aged the chancre is large and "beefy," often phagedenic, and not infrequently is mistaken for malignant disease if situated extragenitally. The induration is marked and persists long after the lesion has healed. This feature however, is not always confined to the chancres of aged persons. I have seen this nodular induration continue for over a year in a man twenty-seven years old. Although large and apt to show destructive tendencies, the chancre in the aged is of slow evolution and heals only after a protracted time. This was observed by Quinquaud many years ago, and with him I am in full accord. The lymph ganglia also show more induration than in younger individuals, and this applies not only to the glands in the immediate vicinity of the sore, as in the groin—the "pleiades of Ricord"—but those remote from it, as the epitrochlear and cubital glands. This glandular hardness also persists indefinitely.

The secondary eruption appears early and is almost always papular. The roseola which is so typical of beginning secondary syphilis in younger persons is conspicuous only by its absence. Papular syphilides of the palms of the hands and of the soles of the feet are frequently concomitant with the generalized papular eruption. Mucous papules on the buccal and lingual surfaces are also prompt in appearing, but strange to say, these lesions so typical of early syphilis are hardly ever found about the genitals or anus. Aside from the mouth and tongue they are most frequently found between the toes. A symptom of this stage is iritis. Lebard observed it in one-third of his cases. It is extremely characteristic of senile syphilis; so much so that it may be regarded as pathognomonic.

As soon as the secondary stage, as manifest by the eruption, is ushered in, the general health, which previously may have been excellent, undergoes a decided change. The patient rapidly becomes asthenic and complains of anorexia, insomnia, headache and vague pains in the limbs and joints, loss of flesh—the last is a symptom which should always cause alarm in the aged as it means that the vitality is ebbing and in consequence is no longer able to sustain the body weight. This profound cachexia which so quickly and suddenly supervenes is characteristic of the toxic effect of the disease in the aged. I wish to emphasize this, because it is nearly always present and unless promptly checked by antiluetic and supportive treatment will in a short time—a very short time in many instances—overwhelm the patient and cause death. While it is to be understood that not every aged luetic so reacts, yet in the majority this swift deterioration of the bodily forces is so marked that it may be considered a pathognomonic symptom of recently acquired lues in the aged. As noted by Quinquaud, the blood of aged luetics shows a constant and decided fall in the number of the red blood corpuscles—in many instances below two million—and an excessive diminution in the percentage of hemoglobin and of the albumin in the serum.

Tertiary cutaneous manifestations are frequent and precocious. Unless properly treated they may be very destructive. Before the days of the Wassermann these lesions were not infrequently mistaken for malignant growths, as has been reported by Tillaux, Mercklen, Sigmund and others. Lesions of the cerebrospinal axis, such as acute meningitis of the base or of the convexity, gummatous infiltrations of the nerves of special sense, hemiplegia, monoplegia and spastic paralyses, are frequent and often of startling promptness.

That syphilis of the aged attacks in the manner described can be readily appreciated if we realize certain determining factors which are present in old age. We must remember that in old age the body represents a machine that has been running for many years. It is worn out. If it had any flaws at the beginning they will be showing now; any diseases acquired during the journey of life will also be exerting their maximum effect. The cells composing the various tissue planes of the body are undergoing retrograde metamorphosis. Their tendency is toward fibrosis—sclerosis—shrinkage. The vital urge, once so full and overflowing, that enabled the body to overcome or withstand the noxious elements of disease, is slowing down. The mighty army of phagocytes that once could be marshalled in battle array are now but a broken remnant of war-worn veterans *sans morale, sans elan.* Thus it is when the diathesis of syphilis is grafted on a body rendered decrepit by arteriosclerosis, fibrotic kidneys, or kidneys permanently crippled by an ascending infection caused by a cystitis due to an enlarged prostrate or a strictured urethra, dyscrasias of rheumatism or gout, cardiopathies involving the musculature—myocarditis, or fatty degeneration—or the valves, chronic dyspepsia and constipation, pyorrhea and decayed teeth. There is ample reason why the disease is fulgurant and fraught with danger.

The treatment of syphilis in the aged should be attended with more circumspection than in younger persons. The reasons for this are the probable state of the kidneys and the cardiovascular system in the aged. It must not be forgotten that in order to combat the disease we must introduce powerful—I might say toxic—agents into a body debilitated with age as well as with disease. Treatment should commence as soon as the diagnosis is made; but along with the diagnosis there should also be a strict inquiry into the state of the kidneys and of the heart and vessels. Neosalvarsan should be given in every instance. The reason for this is that it can be given in a small amount of fluid and therefore will not strain the heart or arteries as when large amounts of fluid are used as in old salvarsan. The dose should be smaller also. If the weight of the patient indicated a dose of 0.6 gm. the dose should be 0.5 gm. or 0.4 gm. The intervals of injection should be three or four days apart. I am in the habit, in order to get the full sterilizing effect of salvarsan, of giving the injections on three consecutive days, but in the aged this cannot be done because it would be too much of a strain on the kidneys. As to the number of injections, it is impossible to say. The symptoms must be controlled, which includes the prostration, which should be replaced by a sense of well being. Supportive treatment should be given along with the antiluetic treatment. This includes tonics, abundant, concentrated nourishment—egg yelks, milk, milk sugar and small quantities of whiskey, fresh air and quietness of mind. I do not recommend mercury, since we have organic arsenic at our disposal. Iodide may be given with advantage in the later stages of the disease, and when given, the sodium salt should be the drug of choice. I do not often use it since the advent of neosalvarsan.

Syphilis in the old as in the young should be attacked boldly and persistently; but the attack should be planned with more caution as it were. Prompt diagnosis and prompt treatment will in nearly every instance save these patients from the ravages of the disease.

SIMPLE EVERYDAY SCIENCE ABOUT YEAST.

By LEONARD KEENE HIRSHBERG, A.B., M.A., M.D.,

NEW YORK.

SUCH as have need of milk, and not of strong meat, may learn much from the life history of the micro-small yeast buds.

What man is there of you whom, if his son ask bread, will he give him a stone? Or, if he ask a fish, will he give him a serpent? There are such men as you know. They will turn against their own flesh and blood, and even feed themselves the very food that is worst for them.

The old platitude, "What is food to one man may be fierce poison to others," is seldom considered by many who take recommended medicines that are never food at best, and only too often poisons to many. A food, however, that has proved to be almost, as Iago says, "as luscious as locusts," a morning incense in fact to most epicures, is the little compressed cakes of yeast obtainable at any grocery.

Yeast, you know, can be grown by anyone. High school students commonly plant it and grow it for study and experiment.

Under the 1000 fold magnification of the microscope, the tiny individual yeast units resemble oval or beer barrel shape bubbles with smaller bubbles or buds bulging out from each. It requires about 350 yeasts and buds to make an inch. That is to say, each one is a little larger than one-five-hundredth of an inch.

If one of these tiny units called "cells" is placed in sugar water, malted water, or some other simple fluid solution, it will begin to nurse or suck in nutriment through its bubble-like walls and form buds, which soon separate and in turn form buds of their own. This is the way they multiply and replenish the earth. The wall around the lymph-like plasma in the yeast's interior bulges out like a smaller bubble. This is the bud which swells by nourishment until it is large enough to break loose and thus itself become a parent which repeats the performance. Thus, in the proper pabulum, there will very quickly be a myriad of yeasts thriving, budding, and reproducing in kind, and in some hours there will be over a million of these little individual yeasts, enough to make the tin-foil covered squares of yeast obtainable at your grocer's.

In general, any one may make yeast by planting a non-contaminated yeast on a grain mixture of corn, rye, and barley-malt of the best quality. This grain is, in the best yeast factories, cleansed of all contaminating fungi, moulds, bacteria, microbes, animalcules and dust by special methods and kept so until sent to the mills. It is then cleaned again even more rigidly.

Before the yeast is put in its happy hunting grounds—the mash or nourishing solution—the grains are soaked in water as nearly sterile by filtration as it is possible to get it. This softens the sweet starch in the cereals and allows the yeast to absorb it from the solution through its walls all the more easily.

Corn is mashed at great heat, the rye is put in after the corn is "cooked," and finally, when cooler, malt is added to turn the starch of the corn and rye into sugar. There is in malt an "enzyme" or pepsin-like substance, which converts starches into sugar just as the saliva does.

There is no alcohol in the mash. The best cultivators of yeast add lactic acid, sour milk and certain bacteria to the mash to help keep it pure. Of course, this gives it a sour taste, but these bacteria make the solid, albuminous stuff the more easily digestible to the baby yeast buds.

Lactic acid, the sour-milk acid, is very helpful to the growth of yeast. When this is next filtered off, the mash is run into tubs with perforated bottoms, which allows the "wort" or clear fluid to pass through and holds back the thick grain. The "wort" is then heated to very high temperatures, finally cooled, and pipe-lined off into tanks 20 feet high.

Now at last, the domestic scientist, the student, the home-maker, or the manufacturer has a practically clean, sterile fodder—the clear wort—ready to receive a pure culture of yeast. The yeast is introduced into the sweet nectar, the

wort, and oxygen in the guise of air is forced into it. Thus "mother culture" or "mother yeast" begins to grow and bud and fructify over the face of the sweetened water. With the proper condition of temperature and air, an immense amount of the little yeast plant will have grown in twelve hours.

Then comes the task to separate the yeast substance from the "wort" or sugar water. It is accomplished in the way that cream is separated from milk—by the so-called "filter presses." The excess moisture and water is thus compressed from the yeast, which is retained between the large slabs of the press between cloths. Finally it is removed from the presses and put in refrigerators.

Yeast is alive, easily perishable, and just as easily contaminated. Millions of homes now depend on yeast for health and beauty and many physicians advise its therapeutic use in the home. Its value as a health preserver and a food now really exceeds its employment by housewives as a necessity for bread making.

Obviously, the dirty, ugly looking, huge hunks of yeast sold in many shops do not measure up to the necessary, scrupulous cleanliness which is required to avoid the chance of contamination. Yeast, like milk, ought to be certified as to its freedom from germs. It is a complete food, as easily polluted as fresh milk. Unless you can assure yourself that the yeast you eat before each meal and in your bread is made in tanks, pipes, and presses that can be and are sterilized with live steam, you may defeat the great good which pure fresh yeast will generally accomplish.

The small square of yeast which you ought to eat before your meals ought to be snugly in your grocer's or baker's refrigerator, fresh, firm, effective, active, and with its vigor and growth unimpaired. This is all accomplished, if delivered in its fresh state each day, iced and refrigerated. The long cakes—resembling, but larger than bricks of ice cream—are easily sliced with wires into small cakes and wrapped in tin-foil.

The dietetic and health value of yeast has been discovered in recent years, not by careless observers but by some of the most eminent, painstaking, diligent, unprejudiced research workers in the world. Each more or less without the help of the other and independently has found that half a yeast cake a day aids the health, growth. vitality, weight, repair powers, and personal beauty of those who eat it regularly.

Among the unbiased and distinguished investigators who have brought this to light from such places as Yale University, Rockefeller Institute, Columbia, Jefferson, Fordham, Johns-Hopkins, Minnesota Experiment Station, and the U. S. Government, are Casimur Funk, the discoverer of vitamines; Osborne, Mendel, Levene, McCasky, Hawk, Bergheim, and many others. They proved that yeast is, like milk and honey, a complete food in itself. It also contains vitamines. It relieves constipation. It adds weight and growth. It helps the red and white blood corpuscles to digest and to destroy the pathogenic germs causing pimples, boils, and other more serious skin troubles as well as those which are mere blemishes.

For infants, yeast is a pabulum superior to all but pure milk, and a great adjunct to boiled and pasteurized milk as a remedy and preventive of scurvy, rickets, backwardness of growth, flabbiness, obesity, and other maladies. Moreover, in adults it helps to ward off beriberi, pellagra, constipation, hemorrhages, certain joint pains from sugar disorders, the deformities of rickets, gout, and other digestive and deficiency diseases.

No small value of the staff of life—bread—depends upon the yeast planted in the gluten and starch as dough. It was a common saying among the Puritans, "Brown bread and the Gospel is good fare." They never really knew why. Scientists have at last uprooted the facts to prove this.

859 Seventh Avenue, Corner Fifty-fifth Street.

ALLERGIES IN CHRONIC DISEASES.

By J. B. LUCKIE, M.D.,

PASADENA, CAL.

Sensitization of tissues to specific proteins has been demonstrated conclusively, but the use of protein preparations as a diagnostic measure in various indications is yet in its infancy. The purpose of this paper is presentation of what the writer considers one of the many indications for their use.

We believe that illness of a chronic nature induces allergies of different types, perhaps through the fact that the energy of the body is being directed toward combating infection, or bacterial protein of a more or less permanent nature, and its attention, so to speak, is directed from occasional proteins or special toxins with which that body may at times come in contact. In this paper the entire field of proteins is included. Those prepared from the animals (dermals), from foods, and from pollens, for the pollens are after all nothing more than the spawn of the plant, and should be looked upon as proteins.

Many of the interruptions, or so-called exacerbations, in the course of chronic illness can probably be explained by allergy. The patient can be made more comfortable, and the doctor, too, and perhaps the prognosis improved or altered entirely where this is proven.

The findings of the writer in some cases have been fairly simple, while in others the problem called for prolonged study and some, although seemingly anaphylactic, were so baffling that the etiologic factor could not be found.

In cases that are successfully worked out, the patient feels something real is being done for his prolonged suffering and he is encouraged to fight; faith in the profession is restored, and the physician has something worth while to work upon. It is the writer's opinion that the sensitizations are commonest in respiratory infections, and in the advanced tuberculous, unfortunately, the prognosis is so bad that little change can be expected in that stage of the disease. No claim whatever is made for the use of proteins therapeutically. All that has been done is the removal of the offending agent, thereby making the course of the disease smoother and the patient more comfortable. We do not know what might be done in chronic disease that has induced sensitizations by using solutions of the

proteins in a therapeutic way. All that we have done has been done for the comfort of the patient, rather than to affect the ultimate outcome.

The following briefly sketched cases will illustrate the point.

CASE I.—Male suffering from chronic bronchitis and frontal sinusitis which caused trouble with each fresh cold. By study it was found that clams or shrimps and often Irish potatoes in his dietary seemed to make the bronchitis very much worse and on one or two occasions the attack resembled asthma. He gave a mild positive reaction to cutaneous tests of clam and a strong positive to shrimp but a negative to potato. Elimination of these foods from his menu seems to have materially reduced the number of his colds and added greatly to his comfort. He had been a fairly frequent eater of these foods.

CASE II.—Young woman sent to a sanatorium for tuberculosis. Recurring rhinitis followed by increase cough and expectoration made her course a miserable one indeed. Finally it was noticed that the odor of celery made her sneeze, and it was following a meal containing celery that she had a severe rhinitis and bronchitis with increase of sputum. A cutaneous test of celery was positive. Total elimination of this vegetable from her food made her more comfortable and reduced the sputum to less than one-half. She was dismissed from the sanatorium as moderately improved, and was lost trace of for about six months, when she was seen and reported that she was free from her repeated colds and bronchial attacks, and that she had embraced Christian Science and was perfectly well although she had never eaten celery or even come in contact with it since the test.

CASE III.—A middle aged woman working in a ladies' clothing shop came to the office stating that she had had tuberculosis years before, but that it had been healed and was giving her no trouble, whatever, she felt she was not a danger to others but was sure her employers were viewing her with suspicion on account of frequent bronchial attacks, which caused considerable raising and often resulted in asthma; she was terribly worried for fear she would lose her position on account of the impression the attacks caused on her coworkers and the trade. Examination of the patient and prolonged observation proved that she was an old tuberculous case of an inactive type. The left upper lobe was well fibrosed, large bronchial rales were miscellaneously scattered throughout the lung. Dry rales at the base of the old lesion. Sputum was negative on repeated examinations. There was no marked variation in the temperature curve over a two weeks' period. One of these attacks occasioned a visit to her home and it was found that she owned a peripatetic cat and it was thought the attacks might correspond to the feline's home-comings. Cutaneous test with the cat hair product gave a decidedly positive reaction. The house and its furnishings were vacuum cleaned, Tabby was sent to the S. P. C. A., the patient's attacks disappeared, and the woman retained her job and her peace of mind.

CASE IV.—A middle aged woman suffering from pulmonary tuberculosis. Every convenience was afforded her. She was handled under seemingly ideal conditions. One day she was moved from one room to another on a cot. Two days later her nurse reported an acute cold with coughing and sneezing and blood in the sputum, probably from the strain of sneezing. She was feeling generally miserable. Inspection of the room showed nothing—checking the diet did not enlighten us. The following day she had a frank hemorrhage. While going into the house, the writer noticed a small red trumpet flowered vine climbing the wall under her porch. A bit of pollen was gathered from the blooms by brushing off the anthers with a camel's hair brush. This was mixed with a small amount of tenth normal sodium hydroxide solution and a cutaneous test was made upon the writer, the sister of the patient, and the patient. The first two were entirely without a reaction, proving that the pollen was not toxic of itself. The patient gave a very large wheal that wormed out in all directions. The plant was cut away, the room was well scoured, and all the hangings were removed. Within twenty-four hours she seemed practically comfortable, although the bleeding continued. She lived only four months longer, but was entirely free from this unpleasantness during the time remaining for her. She had had previous attacks similar to this that were etiologically undiagnosed. Early knowledge of them might have prevented her hemorrhages and changed the prognosis of her case.

It is realized that in all of these cases the sensitization may have existed previous to the outset of the infection for which the patients presented themselves for treatment. If so, there was no definite history to prove it. All were questioned on the subject and only one gave a history (Case IV), and she said she thought she used to sneeze when wild flower picking. It may be that the allergies play a part in preparing the ground in which acute infection is sown and help its growth to chronicity.

Conclusions.—Sensitization to various proteins is probably developed in chronic infections, especially those of the respiratory tract, more often than in the normal.

All increases of symptoms in chronic disease should not be pronounced exacerbations of the disease per se, but other causes should be thought of first.

Chronic sufferers can be made more comfortable, and the prognosis perhaps changed in some, by finding the real causes of so-called exacerbations.

207 DODWORTH BUILDING.

Medicolegal Notes.

Finding as to Fractured Skull Held Not Sustained.—In a proceeding for compensation under the New York Workmen's Compensation Act the evidence showed that the claimant on December 29, 1918, in the course of his employment, hit his head against a desk. He worked regularly thereafter until January 16, 1919. At the time of the hearing he was suffering from encephalitis. The Industrial Commission found that this disease was "caused by a fracture to the base of the skull, sustained by him when he hit his head." The New York Appellate Division on appeal found that there was no evidence of a fractured skull, and that the evidence was to the contrary. At one stage of the disease the physicians thought the symptoms indicated a fractured skull, but subsequent developments caused them to change their opinion. The court was of opinion that a tentative diagnosis in a partially developed case, subject to future developments, and which was changed by the later history of the case, could not have any probative force. At most a statement of a witness out of court, inconsistent with his testimony, discredits the witness, but is never received as evidence of the fact contained in such inconsistent statement. No physician in this case had ever testified to a fractured skull, and no physician connected the present disease with the blow to the head. The commission, in its effort to make such connection, was held to have based its finding on the erroneous hypothesis of a fractured skull, of which there was no evidence. The award was therefore reversed. Kellogg, P. J., and Kiley, J., dissenting.—Donovan v. Alliance Electric Co., 191 App. Div. 303, 181 N. Y. Supp. 823.

Compensation for Inguinal Hernia—Attempted Release of Employer.—The California Supreme Court holds that an employee was entitled to compensation under the Workmen's Compensation, Insurance and Safety Act of 1917 for inguinal hernia sustained during the course of employment, notwithstanding his agreement, made at the time of employment, releasing the employer from any claims arising on account of hernia. the existence of which then appeared as the result of a physical examination; such an agreement being ineffectual, under Section 27a, to exempt the employer from liability for compensation under the act.—Hines v. Industrial Accident Commission (Cal.), 188 Pac. 277.

SENILE PERNIO.

CHRONIC senile chilblain is a much neglected minor medical topic, although not unimportant. The lesion is far from being similar to ordinary pernio met with in the young and in adults. Its nature is probably quite different because in reality the lesion is based upon a state of asphyxia of the limbs, accompanied by trophic changes with a chronic evolution, and is excited by cold. Permanent acroasphyxia and slowly progressive trophic disturbances —such briefly is the foundation of the lesion under consideration. All the fingers and even the thumbs are usually tumefied; the skin is rarely hard, often even it is abnormally soft; the cutaneous folds are effaced while the epidermis is thinned as if stretched. The fingers are a violet red, becoming almost black under the influence of cold. However, the tint is not always uniform because ill-defined maculæ of a more marked purplish tint can be detected. The swelling and cyanotic hue, more marked at the ends of the digits, occupies their entire length and to a certain extent invades the dorsal aspect of the hand. The integuments are always cold to the feel and the patients complain of a benumbed feeling. The fingers are semi-flexed, their mobility is limited, and any delicate work is out of the question. This condition becomes evident at the beginning of winter, subsides with the early heat, and almost completely disappears in summer.

To this basic circulatory disturbance accessory lesions become added. Erosions occasionally arise, especially over the exterior surfaces of the joints, but they are less deep and much less frequent than ulcers following chilblains in young subjects. At the extremity of the pulp small subepidermic abscesses are sometimes seen which are extremely painful and end in lenticular ulcers and small depressed cicatrices similar to those observed in Raynaud's disease. The nails are short, sometimes broader than they are long, undermined at the ends often to a considerable extent. The sensibility is preserved and if occasionally it is dull, this is due to the age of the subject. Pruritus, so common in the juvenile form of pernio, is wanting, but on the other hand pain is complained of similar to that of abscess in the pulp of the finger. When the acroasphyxia decreases with a change of season, the pain disappears, the swelling subsides, and the violet color fades out, but the nails remain deformed and the fingers are always somewhat cold.

When once the process has become established there is hardly any tendency for it to diminish. It continues to reappear with the advent of each winter, but there are, however, cases in which an amelioration in the general health has as a consequence a decrease in the gravity of the winter attacks. It is remarkable that in nearly all these cases the lesions are observed on the fingers. The feet are, in fact, much less frequently involved, and although they may offer a certain degree of cyanosis and coldness, these phenomena are less marked than on the hands and the patients do not complain of them. On the other hand, senile pernio on the ears may be observed, in every way analogous to other forms of senile chilblain, and finally end not only in cicatricial atrophy of the skin, but in calcification of the cartilage of the pinna of the ear.

CHEMOTHERAPY.

RICHAUD in a lecture on this subject published in *La Presse Médicale* for September 4, 1920, xxviii, 63, sums up as follows: Researches by Ehrlich and by Mouneyrat led to the discovery of a treponemicide activity of certain organic arsenical compounds. It is likely that in time other elements may be incorporated into similar compounds with analogous therapeutic effects—mercury, for example. But it is not necessary that such sterilizing remedies shall have an inorganic constituent, for we have in quinine and emetine two purely organic protozoicides. In other words, it is not necessary that a highly toxic substance be in the molecule. Why may we not have a treponemicide of purely organic composition? The future must seek such a consummation.

The author is led to look into the past for the purpose of tracing the evolution of what we now term chemotherapy. The first move in this direction was made by Cadel in 1760, whose "liquor fumans" was clearly an organic arsenical compound. Nothing new happened along this line until 1837, when Bunsen discovered cacodylic acid. Over 20 years later Bayer discovered methylarsenic, while in 1863 Béchamp, one of Gautier's early teachers, discovered arsenaniline. Up to this time such combinations had been looked on as laboratory curiosities, but Gautier, who came next, was led to surmise the existence of therapeutic possibilities in these substances. He showed that arsenic may be present normally in certain human organs and then proceeded to test the cacodylates as drugs. The author would award to him more credit than to Mouneyrat or to Ehrlich, for despite the great practical value of the labors of these scientists Gautier was the real pioneer on whose foundation the others built. It was he who first showed that organic arsenicals were less toxic and more effective. Mouneyrat, whose fame has been eclipsed by Ehrlich and his associates, worked on these problems independently and discovered hectine; but Béchamp had discovered under another name the substance later known as atoxyl in 1863, as already stated. Laveran in 1903 had shown the trypanocide properties of inorganic

arsenic in sleeping sickness. Ehrlich took up the study of atoxyl in 1903 but was dissatisfied with its action in the clinic and dropped it for 2 years, so that the Englishman, Thomas, seems to have deserved at least equal credit for the introduction of the drug into the therapy of both syphilis and sleeping sickness.

Articles like the one under review are clearly written with a view of upholding French prestige in the sciences, for the French now realize that it was largely their own fault that German science was better advertised before the war. Such articles are rather numerous at present and doubtless will increase rather than diminish. They may be classed as legitimate propaganda because absolutely free from misrepresentation. There is, of course, no attempt to present the German side, but so far as we have noted there is no deliberate suppression or misstatement.

RADIOSCOPY AND RADIOGRAPHY OF THE SPLEEN.

THE present means at our disposal for the clinical exploration of the spleen are susceptible of furnishing excellent data, but they are not to be implicitly relied on in each case, because they expose the clinician—as do all methods of exploration—to much uncertainty and to many mistakes. The radiological study of the spleen furnishes another diagnostic element that must not be neglected in practice. It completes the clinical examination of this organ and facilitates the recognition of affections involving it, and therefore procures the means of making a precise diagnosis; that is to say, the differentiation of affections seated in those viscera in proximity to the spleen.

Clinically, the spleen in the normal state may be percussed but it is inaccessible to palpation, hidden as it is under the diaphragm and protected by the thoracic walls. The data this furnishes are consequently incomplete. Radiologically, the opacity of the spleen stands out somewhat against the transparency of the overlying structures, but without technical contrivances it shades off on the radiograms and becomes mingled with the shadows of the adjacent organs. Gas distention of the stomach, as well as of the colon if necessary, reveals a light area on the plate showing the situation of the organ and by contrast the situation and size of the spleen, which gives a dark area on the plate. In some cases the gas distention need not be artificially produced because it is naturally present and is distinctly manifest in children, as well as in adult aerophage individuals. The exact shadow of the stomach showing its situation and displacements may also be obtained by radiography and radioscopy after a bismuth meal.

Radioscopy of the spleen should be done successively in profile, from the back, and in the intermediary oblique positions in order to see the organ on the screen in all its incidences. Orthodiagrams can thus be taken at the same time which will allow the surgeon to formulate an opinion. Radiography afterwards will fix the shadows seen upon the screen. It should be done with the subject in the upright position, seated and recumbent, but it must be done with a powerful apparatus because to give good results the exposure must be very short. In these circumstances only will a sufficiently distinct shadow be seen upon the plate because otherwise the physiological movements of the diaphragm would destroy the clearness of the shadow.

These means of investigation with Roentgen rays will allow one to observe *de visu* the changes in position, size, and shape of the spleen as well as its mobility or fixity. It likewise reveals its relationship to other organs that surround it, and when in a pathological state to recognize exactly if the spleen or neighboring viscera are the seat of the morbid process of which the patient complains. Briefly, for the clinician these methods represent a marvellous auxiliary which should invariably be consulted, as it will certainly complete the clinical examination when it does not do more.

FILARIAN ITCH.

UNDER the above title Montpellier and Lacroix have described in *La Presse Médicale* for September 1, 1920, xxviii, 62, an affection which they encountered among the negro troops from Western Africa. The cases were originally diagnosticated as ecthymatous scabies, but having proved refractory to antiscabic remedies it was then learned that the affection was due to the embryos of the *Oncocerca volvulus*. It is a strange coincidence that another skin disease, due to the same cause but of quite different character, has recently been studied in Guatemala (see MEDICAL RECORD, September 18, page 484). The marked difference between the two affections makes it probable that the Central American filaria is not *O. volvulus* but, as suggested by Brumpt, a special variety which he terms the *O. cæcutiens* from its ability to produce blindness in association with facial erysipelas. In the latter affection adult filariæ of both sexes are found in cutaneous cysts; in filarian itch the embryo seems to be the principal factor in causing the disease, although there are certain subcutaneous fibrous nodules which contain both sexes of adult filariæ. The authors describe filarian itch with extreme minuteness but it must be remembered that in the black these lesions would differ notably in appearance from the same affection in the white. Itching is a marked feature, and the consequent scratching leads to urticaria and various artifacts in a people who are naturally disposed to ecthymatous and other pyogenic lesions. There are no embryos in the blood, and it is evident that propagation occurs through the lymph channels. Enlargement of the lymphnodes is almost always present.

The authors attempt a sketch of our earlier information along the same lines. In 1875 O'Neil first described the so-called craw-craw, a condition much resembling scabies, which he claimed was due to the embryo of a filaria. He was evidently ahead of his time, for Manson, after studying the new

disease, asserted that the embryos were not in the skin proper but in the cutaneous blood vessels, from which they were extracted by the curette. The report of O'Neil was also lacking in scientific quality, so that the only credit handed down to him is for the name of the affection. But craw-craw is naturally a generic rather than a specific term, and since it doubtless includes filarian itch, the latter term might now come into use. Much remains to be done before the disease can have its autonomy proved, say the authors, who wrote in ignorance of the filarian facial erysipeloid of Guatemala. Under treatment the authors do not expect much from the organic arsenicals which have done good work in Guinea-worm disease. The subcutaneous fibrous nodules which contain the adults should be treated directly, for the embryos do not appear to develop in the cutaneous lesions and doubtless escape with the pus.

NON-MALIGNANT OMPHALONCUS.

THE umbilicus is the seat of certain neoplasms of entodermic origin which take the development in the embryonal remains of the abnormally persisting allantoid and omphalomesenteric ducts. During the development of the abdominal parietes, umbilicus, and cord, these ducts undergo an elongation which ends in their rupture, followed by the disappearance of their component elements. But occasionally the omphalomesenteric duct persists in various stages of its development, in the midst of the umbilical cord. When it persists in complete form the intestine opens at the umbilicus by a diverticulum—Meckel's diverticulum—which in other cases may not adhere to the umbilicus, ending in a cul-de-sac within the abdominal cavity. When the retrogression is more accentuated only some remains of the omphalomesenteric duct persist in the thickness of the umbilical cord, and it is these that give rise to an umbilical adenoma of the intestinal type.

The congenital tumor usually makes its appearance during the first few weeks following birth, but it may be overlooked in early life and not be discovered until the child is a year or more old. It is sometimes sessile, the size of a small pea or a cherry, at others it is pedunculated and projects at the umbilicus in the form of an appendix with a smooth swollen end. Occasionally the growth is composed of a central tumor surrounded by small accessory tumors, placed like a crown around it. Five of these accessory tumors were noted in a case recently reported by Bérard and Dunet, of Lyons.

The histological structure of non-malignant tumors of the umbilicus is that of the intestinal walls with all their elements—a superficial mucous layer with its characteristic epithelium, tubular glands similar to those of Lieberkühn, lymphoid tissue, and unstriated muscular layer.

The treatment consists in total omphalectomy, the only procedure which assures a free excision of the growth radically removing the omphalomesenteric débris susceptible of developing later on, while at the same time the intraabdominal malformations resulting from this anomaly can be properly dealt with, which otherwise might be the cause of occlusion from kinking or strangulation. The possibility of the transformation of a non-malignant omphaloma into a malignant growth is likewise a consideration favorable to free excision of this congenital tumor.

GANGRENE OF THE SULCUS PENIS AND SCROTUM DUE TO THE BACILLUS PERFRINGENS AND SEPTIC VIBRIO.

MASSIAS reports a case of the above affection in the *Journal de médecine de Bordeaux* for June 25, 1920, xci, 12. Since 1883, when Fournier described a case of fulminating genital gangrene, many like cases have been placed on record, but the nature of the process has remained obscure. In a few cases it has followed upon coitus or other external violence, but on the whole it cannot be brought into relationship with exogenous infection. It is far from apparent why in one case the penis, in another the scrotum, in a third case both structures should be involved; nor is it obvious why some cases appear to be instances of gangrenous erysipelas and others without the latter element. The patient in the present case was a man of 52, with ancient syphilis, and an inveterate alcoholic. The affection began with a redness of the prepuce which developed into gangrene and involved secondarily the entire sulcus penis. On the fourth day there was a sphacelus on the dependent portion of the scrotum. The case must be distinguished from the phimotic type, for there was at no time any difficulty in retracting the foreskin. There were no active manifestations of syphilis, which dated back ten years, but the Wassermann was strongly positive. There was no history of recent venereal exposure. Pus from the sulcus and the serosity of the scrotal lesion showed *Bacillus perfringens* and the septic vibrio. During the war these anaerobes were frequently accused in connection with gangrene. Treponemes and the Ducrey bacillus were alike present. An erysipelatous blush appeared over the buttocks but lacked something of being true erysipelas. There was no inguinal adenopathy. Hemoculture was negative. The case ended fatally. The author has recently seen two cases of gangrenous erysipelas of the scrotum, one of which recovered, and regards this affection as distinct from the present case. On February last Bloch and Schulmann presented at one session of the French Dermatological Society no less than four cases of perfringens gangrene of the sulcus penis.

AN ANOSMIC-EPILEPTIC FAMILY.

ALIKHAN of Geneva gives an account of this family in the *Revue de Laryngologie*, etc., for June 15, 1920, xli, 11. The family in question had a membership of 30 in 1914. All the members were in good health save that 2 were epileptic. Aside from frank epilepsy, however, there were cases of temperament which are closely affiliated with that malady. Thus one member was very impulsive, another irritable, a third changeable with brutal phases, etc.

The family sprang from a woman who married twice and had two sets of children. Nothing is known of the antecedent generations. By her first marriage she had one child, an anosmic daughter, who bore 8 children. These comprised six simple anosmics, one hyposmic, and one anosmic-epileptic. By her second marriage she had three children, of whom one was an anosmic. This one married and gave birth to three children with olfactory anom-hyposmic. The second child, while herself normal, gave birth to three children, one of whom was an alies. The third child of this brood was an epileptic dement. To sum up in the author's words, there was a family membership of 30, of which number one-half had troubles of olfaction, while, as stated, there were 2 epileptics. Transmission was effected by the female line entirely, but as none of the males married this fact loses its force. The association between anosmia and epilepsy is also seen in post-paroxysmal anosmia, which is sometimes encountered. The author's attempts to associate anosmia and dementia failed because an investigation of numerous cases of precocious and paralytic dementia did not show much incidence of troubles of smell.

Psycholepsy.

This term was devised by Janet to denote mental attacks in which there occurs a modification of the psychic tension. In *Le Progrès Médical* for July 17, 1920, xlviii, Laignel-Lavastine discusses the psycholeptic subject. The question is a large one, for many mental experiences of very different natures may be brought under this head. Many of these figure in psychological fiction, as when of two friends on their way to dine together one assassinates the other without motive. Such experiences usually fall under the head of psychic epilepsy and mental epileptic equivalents, but this is but a single aspect of psycholepsy. Others are presented by hysterical subjects and those in the hypnotic state; others again in the visions of ecstatics and in hallucinations, in the results of sudden mental trauma, even in revery and distraction and other every-day phenomena. In altered psychic tension we see one object and identify it mistakenly as another. The sense of unreality which overpowers at times belongs here. The mere repetition of a certain word may cause us for the moment to forget its meaning. Closely allied is the feeling of *déjà vue*. In the psychasthenic whose mental tension often relaxes one may see numerous and varied psycholeptic states and in the records of men like Amiel and Oberman, who were typical psychasthenics, one may recognize many such experiences.

Volvulus of an Ectopic Testicle.

Malignant degeneration is not the only accident to which an ectopic testicle is exposed. Hallopeau and Quenu report a case of volvulus followed by testicular atrophy in the *Bulletins et Mémoires de la Société Anatomique de Paris* for May, 1920, xc, 5. The patient was aged twenty-two with a history of right ectopic testicle till the age of twelve when it descended for the first time into the scrotum, but as it was not anchored anywhere could slip back into the abdomen. At seventeen and twenty after accidents the gland ascended suddenly into the inguinal canal with a painful crisis and it became necessary to reduce it. On the last occasion the patient was fighting at the front and was sent back with the snap diagnosis of strangulated hernia. Aside from these episodes he frequently replaced the gland when it slipped upward. In 1919 he had a third crisis much worse than the preceding and was unable to replace the ectopic gland. A diagnosis was difficult and after every other possibility had been excluded the authors thought of torsion of the testicle, but substituted at the last moment the diagnosis of acute tuberculous orchitis. Under ice and rest the condition slowly righted itself. The swollen and tender scrotum became normal and the testicle was felt to be in place. A couple of months later the man returned for examination and while the parts were chiefly normal the testicle was much shrunken in size and did not give the testicular sensibility on compression. It was now evident that the last attack at least had been one of torsion. After castration on the affected side examination of the preparation showed that the accident had been the so-called "low volvulus of Lapointe" which must be distinguished from the so-called high torsion, the latter being much more rare.

News of the Week.

International Society for the Prevention of Tuberculosis.—All nations signatory to the League of Nations covenant and the United States, at the International Anti-Tuberculosis Conference held in Paris last week, organized a permanent International Society for the Prevention of Tuberculosis. Sir Robert William Philip, of Edinburgh, was elected president of the new organization. The first annual meeting will be held in London next autumn.

Food Shortage in Central Europe Affects Hospitals.—William C. Mullendore of the American Relief Administration, who returned recently from an eight months' tour of Czecho-Slovakia, Austria and Germany, reports that hospitals in Central Europe are unable to care for the sick as a consequence of the food shortage. Some institutions have been compelled to close, while others receive only as many patients as they can feed.

"Save the Children" Fund.—This fund, started by Pope Benedict, for the relief of suffering children in Central Europe, is said to have grown to 15,000,000 lire.

St. Mihiel War Memorial Hospital for Children.—Under the auspices of the American Red Cross, and cooperating with the French Government, the Junior Red Cross will finance the erection and operation of a model hospital for children at St. Mihiel, France, in memory of the great American battle effort of the World War.

United States General Hospital No. 43, at Fox Hills, Staten Island, has been closed by the War Department. A part of the hospital facilities will be operated by the United States Public Health Service for the care of wounded ex-service men under the War Risk Insurance arrangement. The hospital, which covers 250 acres and comprises more than 150 buildings, has been inspected, according

to rumor, by representatives of the Ford Automobile Company with the view of transforming it into an automobile factory.

Medical Inspection of New York City School Children.—In a report published recently in the *Monthly Bulletin* of the Department of Health, Dr. S. Josephine Baker and Dr. Jacob Sobel, reviewing school medical inspection in 1919, state that 1846 cases of general contagious diseases were excluded from schools during the year, 149 more than in 1918. In 1919 there were found on "home visits" only 95 unreported cases of major contagious diseases, while in 1918 there were 368. In 1919 there were 237,437 contagious eye and skin diseases found in schools, an increase of 209,991 over 1918. This increase is attributed to the fact that at the first sign of any minor contagion the child is placed under treatment. The Sight Conservation Clinic has 699 cases under supervision and treatment at present, and there are 99 children in blind classes. There were 16,942 visits to the dental clinics during the year. A total of 37,677 visits were made by the medical inspectors. Nurses made a total of 288,158 visits. The number of children under supervision ranges from 4000 to 7000 per nurse. Inspectors held 18,412 consultations in schools, nurses 121,813. A special nutrition survey in forty-three schools revealed a percentage ranging from 17 to 61, or a general average of 32 per cent. malnutrition.

Pneumonia in New York City.—For the six weeks from Sept. 1 to Oct. 16, there were 483 deaths from pneumonia in New York City, this being about double the number for the same period last year, according to Dr. Copeland, Health Commissioner.

Request for Fund for Maternity Nurses Denied.—The Board of Estimate of New York City recently denied the request of Health Commissioner Copeland for the sum of $122,400 for the employment of sixty-eight nurses for maternity work. Dr. Copeland held that this appropriation would reduce the mortality of infants under one year by more than fifteen per cent.

Lectures on Industrial Health and Preventive Medicine.—The Long Island College Hospital College of Medicine announces a course of lectures and practical demonstrations on these subjects for practitioners of medicine, for which there will be no charge. Physicians desiring to attend should communicate with Dr. H. Sheridan Baketel, 350 Henry Street, Brooklyn, N. Y.

Institute on Venereal Disease Control and Social Hygiene.—A tentative schedule of courses has been issued by the United States Public Health Service for the Institute, to be held in Washington, D. C., Nov. 22 to Dec. 4. The Interdepartmental Social Hygiene Board and the American Social Hygiene Association are cooperating in the organization of the Institute.

Harvard Health Record.—Figures made public by Dr. Rogers I. Lee, professor of hygiene, Harvard University, show that the health record of the students in Harvard College is more favorable than in most industries and in the Army and Navy. The average student is absent from college work on account of illness at the rate of seven days a calendar year. The mortality statistics at Harvard for the last ten years show only 34 deaths in the total college population of 22,579, giving a death rate per thousand of 1.8 for the college year, or a corrected death rate for the calendar year of 2.7 per thousand. During the last ten years pneumonia has caused more deaths among Harvard undergraduates than all other causes combined.

"Annual Free Will Offering."—The United Hospital Fund has inaugurated its "Annual Free Will Offering," with the hope of collecting, through citizens, business concerns, trade bodies and churches, the sum of $1,500,000 for the fifty-five non-municipal hospitals of New York and eight of Brooklyn, which give free care to the poor. Officials of the fund hope to raise this amount by Nov. 29. Officers of the United Hospital Fund are: Robert Olyphant, president; George Blumenthal, vice-president; James McV. Breed, secretary, and Albert H. Wiggin of 57 Broadway, treasurer.

Next White House Physician a Homeopath.—Inasmuch as both candidates for the forthcoming presidential election employ homeopathic physicians, it is assumed, with rejoicing, by members of that school that the next White House physician will be a disciple of Hahnemann, instead of a rear admiral.

Drug Cure Clinic Evicted.—Deputy Commissioner Sara Graham-Mulhall, in a recent review of the work of the State Narcotics Commission, told of the difficulties encountered in treating addicts and the general lack of sympathy on the part of the public. Her own clinic, for example, had been driven from place to place by eviction notices, finally seeking refuge in the loft of the Bowery Mission. Only 7,000 of an estimated 20,000 addicts in New York City, she said, had registered.

Mental Clinics.—The Mutual Hygiene Committee of the State Charities Aid Association announces that a clinic will be held at St. Joseph's Hospital, New York City, for the examination and treatment of cases of mental diseases and mental defect among patients who have been paroled or discharged from the State Hospital. The purpose of the clinic, it is stated, is not only to keep in touch with such patients, but also to advise with members of the community suffering from mild or incipient forms of mental disease or nervous disorder which, with the aid of a specialist, may be overcome before a serious stage is reached. It is urged that children who are nervous and unmanageable or who exhibit peculiarities of behavior, be sent to the clinic for observation.

Flower Hospital Appeal.—In an appeal for subscriptions to insure its proper maintenance and to make it possible to add sixty-five beds, Flower Hospital reminds the community that it is the sole ambulance service covering a territory in the heart of Manhattan of over 275 city blocks from the East to the North rivers, with a resident and transient population of hundreds of thousands of people. Although this is a real life-saving public service, it is stated, it is operated at a big loss. A single day's record in the emergency ward shows seven little children brought in with fractured skulls.

First Aid on Pullmans.—The Pullman Car Service is giving the American Red Cross First Aid training to the entire force of colored maids em-

ployed on the transcontinental trains. Several of the women have already finished the course and now carry as part of their equipment the regulation first aid kit. The Pullman Company has arranged with the New York County Chapter of the Red Cross to give the course of training in first aid and home hygiene to some hundreds of maids reporting to its New York terminal.

Pipe Dreams in Danger.—The Pennsylvania Division of the Women's Christian Temperance Union, at its forty-sixth annual meeting held Oct. 20, ratified the national program for a campaign against the use of tobacco.

Obituary Notes.—DR. JAMES A. O'REILLY of Brooklyn, N. Y., died at Middletown, N. Y., October 13, at the age of thirty-three. He was graduated from the College of Physicians and Surgeons, New York, in 1912, devoting especial attention to tuberculosis. He served as interne at the Coney Island Hospital and visiting physician to the Brooklyn Hospital, and was commissioned First Lieutenant, Medical Corps, during the World War. Dr. O'Reilly was a fellow of the American Medical Association.

DR. ALONZO POTTER WILLIAMSON of Santa Monica, Calif., died recently, at the age of sixty-six. He was graduated from Hahnemann Medical College and Hospital, Philadelphia, in 1876, and specialized in neurology. He was a member of the American Medico-Psychological Association.

Obituary.

ISADORE DYER, M.D.

NEW ORLEANS.

DR. ISADORE DYER of New Orleans, La., died of heart disease on October 12, at the age of fifty-five years. He was graduated from Tulane University of Louisiana, School of Medicine, in 1889, served as interne in the New York Skin and Cancer Hospital and lecturer in the New York Post-Graduate Medical School and Hospital, returning to New Orleans in 1892. He became affiliated with Tulane University School of Medicine as lecturer on dermatology, 1892 to 1905, associate professor from 1905 to 1908, and professor from 1908 to the time of his death. He also served as associate dean and dean of the same institution. From 1893 to 1905 he was professor of dermatology in the New Orleans Polyclinic. In 1894 Dr. Dyer founded the first board of control of the Louisiana home for lepers, a work in which he continued to be active and interested. He was a fellow of the American Medical Association, of which organization he was vice-president and member of the Council on Medical Education and Hospitals at the time of his death. He was affiliated also with the American Dermatological Association, the Southern Medical Association, the Association of American Medical Colleges, the American Society of Tropical Medicine, and other state and national medical bodies. During the World War Dr. Dyer served as major, heading the local examining board for the Medical Reserve Corps. After his discharge he was colonel in the new Reserve Corps. Dr. Dyer was editor of the *New Orleans Medical and Surgical Journal* and a frequent contributor to the literature of dermatology and tropical medicine.

Correspondence.

THE CARBOHYDRATES AND ACIDOSIS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Your editorial in a recent issue of the MEDICAL RECORD, "The Cause of Dental Caries," was of interest to me. In 1912 I tried to call the attention of the profession to a condition designated "The Carbohydrate Diathesis"; tried to show that this condition was brought about by a faulty *carbohydrate* metabolism. We all know that the by-products of digestion are a vast number of different acids. The carbohydrates are the source of the larger part of these products; therefore when an almost exclusive carbohydrate diet is eaten, the quantity of these acid products is enormously increased. The continuous production of this abnormal supply of acids finally so cripples the liver that it is unable to perform its function of neutralizing this material; the failure of this neutralization is followed by pellagra, chronic rheumatism, chronic nephritis, gastric ulcer, acne, eczema, pyorrhea, and many other allied conditions. Just so soon as we diminish the quantity, and neutralize the remainder of these acids, all these conditions rapidly improve, and recovery is only a question of time. I have never seen a case of pellagra that was not accompanied by pyorrhea. They both recover rapidly as soon as the normal alkalinity of the fluids of the body has been restored.

In view of these facts, I think Dr. Harry Campbell of London is in error when he says "The jamming of saccharine material between the teeth is the most potent factor in dental caries." I am sure his indictment of the carbohydrates is correct, but I think his theory of method by which the damage is done is faulty. In my opinion it is not by jamming this material between the teeth; but, rather, by the continuous ingestion of the carbohydrates with the above mentioned overproduction of acids.

J. F. YARBROUGH, M.D.

COLUMBIA, ALA.

REGULATING THE MEDICAL PROFESSION.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In its issue of Oct. 18, 1920, the MEDICAL RECORD noted a letter sent over my signature to the members of the Medical Society of the County of New York and to other members of the profession in New York City, setting forth the negative value of the efforts made by existing medical organizations and individuals in combating the enactment of unjust and injurious measures and laws limiting and harassing the legitimate practice of medicine. Among the many letters received in response to this appeal I have selected the following as one calling for publication at the present time when the very existence of the profession of medicine as an independent calling is threatened.

JOHN P. DAVIN, M. D.

NEW YORK.

MY DEAR DOCTOR:

I have read with interest the "Bulletin" No. 2, which you sent me and, although not engaged in the practice of medicine, I still retain such rights, privileges and prerogatives as have been left to me as a graduated and registered physician by latter-day legal enactments.

and I regret as much as you do that these rights and privileges have been so ruthlessly and unnecessarily curtailed through the misdirected efforts of idealists, would-be reformers, and political agitators and place-hunters. Speaking as a teacher in medical and pharmacy schools and other institutions, and as the registrar of the Albany Medical College for over thirty years, and as one who has kept in close touch with educational affairs and particularly with medical education, I am inclined to think that it would be better for the public, and better for the profession, if all regulatory and restrictive legislation of medical institutions and medical practitioners were annulled. I do not think that the effect of such regulation has been to uplift the profession, but that, on the whole, it has lowered it and ranks it with the trades. I think that the prestige, morale and influence of the profession of medicine has declined and that there is more commercialism in medicine than in former times. Quackery has not been suppressed, nor is dishonesty abated, but the regular and honorable practitioners, who constitute the vast majority of the regular profession, have supinely suffered their rights to be abridged and their independent action hampered and improperly restricted by unwise and impolitic legislation and the building up of a bureaucratic system which has put medicine under the control of examining and licensing boards, often incompetent and politically controlled. The passage of antinarcotic laws and such enactments as the Volstead act have well nigh destroyed the right which physicians should never have relinquished, to prescribe any medicinal agent whatever that they deemed proper in any case coming under their treatment.

I am opposed to most, if not indeed to all, the measures which you denounce in the Bulletin No. 2, and to the extension of the control of the profession by the State Board of Health, or other boards now existing or which may be proposed hereafter. My opinions are based upon long observation and careful consideration, and, as I am no longer actively engaged in any kind of medical work I speak as one who has no favors to ask nor axes to grind. I deem it high time that members of our profession awoke to a realization of the conditions confronting them and resented the implication that they are incompetents or crooks. Further regulation, registration, and supervision of regular practitioners should be opposed. Yours very truly,

WILLIS G. TUCKER.

ALBANY, N. Y.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, October 4, 1920.

Causes of Blindness.—The Ministry of Health has appointed a Departmental Committee to investigate the causes of blindness and suggest measures for its prevention. The report of the committee is intended to form part of a comprehensive handling of the blind problem by the Government. With reference to the causes of blindness it is known that inherited venereal disease is an important contributory cause. Accidents account for from 12 to 15 per cent of the blind cases and perhaps in the majority of instances, the accidents could be prevented by the employment of suitable occupational safeguards. Inflammatory diseases, such as measles, scarlet fever, and smallpox, are other contributory causes. It is said that while the committee will probably direct the greater part of their attention to these main groups they will undoubtedly also consider the question of the after-care of the partially blind people, among whom the boys frequently become clerks and the girls needle-workers, really the most unsuitable occupations they ought to follow. The question of the illumination of schools and factories will likewise be discussed and the committee will finally endeavor to find out how it is that so many defective spectacles are supplied to the public.

National Health Insurance.—The aggregate receipts of the National Health Insurance amounted last year to £9,167,552. Of this sum £4,076,810 was paid for sickness benefit; £1,111,200 for disablement benefit; and £921,490 for maternity benefit. The administrative charges reached a total of £2,110,289 or 23 per cent of the receipts.

Opening of the Winter Session of the London Medical Schools.—As usual at the opening of the winter session of London medical schools on Oct. 2, addresses were given by well known physicians and surgeons and by distinguished men and women in other walks of life. At St. Mary's Hospital, Dr. J. G. Adami, vice-chancellor of the University of Liverpool, and for many years professor of pathology at McGill University, Montreal, made the address. Dr. Adami said in part that if England were to keep its position among the nations above all was necessary the spirit of initiative and progress and adaptation to the needs of the new era, and St. Mary's Hospital and Medical School stood to-day as the exemplification of this spirit. That it might be of greater service to the community, St. Mary's had taken into alliance other hospitals and thus expanded notably both its treatment and teaching facilities. It had realized that maternity teaching was an essenial part of the course, and instead of sending its students to an outside institution which it could not control, had established an obstetric department with beds and out-patient clinic in the hospital itself, with results that were as excellent as they were appreciated by the student. It had at heavy cost to itself maintained its independence, and withstood the temptation to obtain aid from the Ministry of Education, with the loss of control and training of its students in their earlier years of medical and scientific study which would have ensued had it accepted that aid, with like independence and like loss of prospective revenue it had not slavishly accepted the scheme of full time professorships in medicine and surgery and establishment of the unit system, but had put into force a scheme of its own which it believed was adapted to its special circumstances and of greater benefit to its students. Doing this, it had for the time being cut itself off from Government aid. Recognizing the demand for medical training for women and the altered status of the sex, it had thrown itself wholeheartedly into coeducation. It had brought its Institute of Pathology into close association with the needs of the hospital, and, as a latest move sympathizing with labor and comprehending that during the coming generation industrial problems must be to the forefront, it was preparing to establish the first chair in industrial medicine in the Kingdom.

Dr. Adami went on to say that the universities and the professional schools of England found themselves to-day in a parlous state. Never indeed had their condition been more parlous. Students were pouring in to all the professions in numbers double those before the war, the demand for extra accommodation had soared to an unheard-of height. Like coal miners and bricklayers, univerity teachers must live, even if they managed to exist on stipends well below the wages received by coal miners. So great had been the increase in the cost of living that whereas a junior member

of the staff was content with £100 a year, his small personal fortune on what he could make by the side, and his expectations, to-day with the rise in the cost of clothes, lodging and boarding, £250 was the minimum that sufficed, and even then secondary schoolmasters with three years' university training were receiving as much and more. Was it a wonder with expenditure rising rapidly quarter by quarter, and income as steadily sinking, the universities and professional schools of Great Britain were at their wits' end? Was it a wonder that realizing the public duty performed by them, and knowing that in other countries, like France and Germany, the State had for generations assumed the cost of university and professional education, the universities and medical schools in their distress should turn to the Government and appeal for further aid? So the vice-chancellor and the university authorities and representatives of the teachers went before the Chancellor of the Exchequer and the Minister of Education, and placed part of their case before him, only to be told by the Chancellor, what was quite true, and to his great credit, that he had done more to aid the universities of England than any previous chancellor, that he was at his wits' end to meet the financial needs of the nation and that he could do nothing to help those who did not help themselves. He as much as directed them to raise their fees, and only when they had done all that was possible to secure income from other sources to come to him again. Immediately following this pronouncement the council of the University of Liverpool, just as did that of the University of London, resolved to follow Mr. Chamberlain's bidding. Here was the tragedy. As a loyal and public body they responded with open arms to the request of the Ministry of Education that they should accept ex-Service Students. They accepted them to the very limit of their capacity. Yet they were told very decidedly that the ministry would not meet the increase in fees of these ex-Service Students already on the roll. Thanks to the decision of the ministry they were now, what with ex-Service and Training College Students, faced with a deficit of nearer £15,000 than £10,000. From having carried out to the fullest extent the advice of the Chancellor of the Exchequer they found themselves, through the action of another ministry, placed in a most embarrassing, not to say ridiculous, position, unless with the full facts before it the ministry, reconsidered their decision. As a vice-chancellor, Dr. Adami was upon principle strongly opposed to seeking help from Government. What through the generations had distinguished English universities and university staffs was their independence of Government and Government control. The Chancellor of the Exchequer, Mr. Chamberlain, had done well to compare the results of English university education with those of the German system, to compare the sturdy independence and resultant initiative of the British system with the formalism and repression of the German machine system. In three years the English scientists not merely caught up but in every instance advanced further those positions in what he might term offensive science gain by the German through thirty years of laborious effort. It was through their subservience as Government officials that the Russian and Prussianized professors supported the military caste in leading Germany headlong into disaster. It would be an evil day for England when her universities and hospitals come under Government yoke. If they were forced to ask aid from the Government let it be with a clear understanding that this was but temporary, and with definitely expressed conditions that their hands were not tied, and that the officials of Whitehall were not empowered to interfere. Let the grants be of such a nature as not to give excuse for interference. The speaker suggested a plan by which this end might be reached. As for the unit system which has been adopted in many of the large hospitals of Great Britain and which has been hailed with pæans of praise Dr. Adami confessed that he was more than a little nervous about this strong movement, he would not say directed from Whitehall, but which had been blessed by Sir George Newman, a movement for full-time professorships in medicine, surgery, and midwifery, and the development of the unit system, which had come to Great Britain from Germany through America. Could this system be securely grafted on the English method of teaching medicine? At this stage it seemed to him that it would be wiser to let others make the experiment, and to observe the results. How had the system succeeded in Germany? The results, it seemed to him, had been very significant, not to say sinister; such results as none of them wished to accrue in the British Isles. The Germans had, it was true, excelled in detailed studies of particular diseases, but where they were to be credited with notable discoveries it was not a little noteworthy that those whose names were known to all were not the university professors of medicine and surgery, were not the clinical but the laboratory men, like Virchow, Koch, and Ehrlich. The less trammeled English system had favored the development of men of original mind, where the German system had repressed it. The German system made for the solitary leader, not for the establishment of schools. Here the human being was the first consideration but in Germany and Austria hospital patients might too often be so many animals. Heedless of modesty and natural emotion, man, woman, maiden, and child were ordered to expose this part or that to the crowd of students, and were subjected to this or that test. They might be a herd of cattle or a company of Prussian privates. The ordinary product of a German medical school had had a far less thorough and all-round general medical training than had the English medical student; he was a poorer practitioner. If the unit system were established the German defects would be encouraged, namely, neglect of good general all-round teaching for all, and over much encouragement of the student to specialize too early in his career. Why adopt this German system which had come to us through the United States when there was an English method, a method on right lines, the beginnings of which were in action in St. Mary's Hospital and Medical School?

At the opening of the Middlesex Hospital Medical School I. Swale Vincent, Professor of Physiology, gave the introductory address dealing with medical education and research and urged medical men to regard every case as a problem. He pointed

out, that most of the epoch-making discoveries in their profession had for some little time no direct application to medical practice. There was room for great improvement in the methods of medical teaching. Students heard so many lectures that they became almost immune to any influence that might be created by lectures, which should be explanatory of laboratroy work; and laboratory work should be considerably increased. The normal should be thoroughly known before the student proceeded to the abnormal. Professor Vincent referred to the lack of public support given to research work at the universities and the "miserable makeshifts" authorities there had often to be content with.

At the Royal Free Hospital School of Medicine for women there was a large gathering of lady students on the occasion of the opening of the winter session. The dean of the school, Miss Aldrich-Blake, M. S., M. D., who presided, spoke with pride of the success achieved by students of the school and she stated that the successes of the past year had been greater than those of any other school. Miss Maude Royden addressed the gathering on "Revolutionary Thought" and said they had achieved little less than a revolution for the world had now passed out of that period when women were regarded somewhat in the nature of natural invalids who were always suffering from "meagrims" and hysteria and similar troubles. That revolution was due to women being now skilled in surgery and medicine. The idea that progress and pain must go together in the staggering proportion that now existed was pure imagination due, she thought to its always having been so in the past. They had got to get into their own minds, and in the minds of the people, that when they wanted to make a new world they could not do it by mechanical means. They could not build a new world by merely turning the old one upside down. That was what appeared to be in the minds of the Russian people at present. When society was turned upside down, as, for instance, in the French Revolution, they possibly did get some little advance if only by the change; but at what an awful cost in suffering and chaos! Those who felt strongly opposed to international war would make no real progress if the only result of their efforts was to provoke a class war. Every effect has its cause, and it was by seeking the truth and finding the cause, and then scientifically applying the remedy, that they could make real progress; and it was revolution in that sense that she commended to the students of the Royal Free Hospital Medical School.

6. Vincent's Angina—Stomatitis. John E. Ganley.

1. A Clinical Apparatus for Measuring Basal Metabolism.—Benedict and Collins describe and illustrate the latest modification of a portable respiration apparatus, which is reduced in weight, and provided with support and stand. Thus modified the apparatus is strictly portable and not merely transportable. Without gas analysis, without weighings of any kind, the oxygen consumption of patients may be studied by this apparatus in the customary ten to fifteen minute periods, with an accuracy fully equal to other standard methods of studying respiratory exchange. A simple method of timing the readings of the position of the spirometer bell eliminates the use of stop watches. Three series of comparison tests on two different subjects with widely varying basal oxygen requirements show that the most satisfactory results can be obtained.

2. Orchitis in Mumps.—Conrad Wesselhoeft, in this second paper, discusses orchitis preceding parotitis, orchitis without parotitis, clinical aspects of orchitis and the pathology of the affection.

3. Treatment of Arterial Hypertension.—John H. Musser points out that in spite of all that has been written and despite the facility with which medical men are accustomed to manage cases of hypertension, several new methods of treating this condition have appeared in the past two years. Particular attention is directed to these newer methods. The writer holds that hypertension for which there is no obvious cause is a symptom, not a disease; and yet it is a symptom which is so closely related to disease that it is not amiss to treat the symptoms. A high pressure, though merely a manifestation of some underlying pathological process, is so frequently the main symptom and the cause of so many closely related symptoms that it has come to be regarded as a definite entity, no matter whether the increased blood pressure is the result of a neuropathy, an endocrine dystrophy, or a narrowing of the smaller elements of the blood vascular tree. It is impossible in many cases, by the ordinary clinical and laboratory tests, to demonstrate renal changes, internal secretory disorders, or other causes to explain the pathogenesis of the condition of high blood pressure. One is accustomed to assume that there is present a glomerular nephritis or a renal sclerosis, yet one is unable to show any distinct evidence of kidney pathology. This absence of symptoms and signs, except those referable to the high pressure, has led to a variety of names being applied to the syndrome—cardiovascular hypertensive disease, hyperpiesis, essential hypertension. The last named is the term most frequently applied to the disorder. By essential hypertension one understands a condition of continuous high blood pressure, systolic pressure over 175 mm. of mercury, of unexplained cause. The patient may have many symptoms referable to the high pressure, yet on the other hand a high pressure may exist without symptoms and only be discovered when making a routine sphygmomanometer examination. Such an individual is objectively though not subjectively sick. The management of the cases is discussed with regard to general treatment; diet; physical effort; hurry, worry, and mental strain; sleep and rest; elimination; hydrotherapy; drugs; reduction of salt and water intake. An illustrative case is reported. The writer concludes that the management of a case of hypertension requires a careful study of the patient. Unless some threatened vascular cardiac or renal catastrophe seems imminent, physical and hygienic measures should be relied upon more than drugs. The reduction of salt and water intake forms a valuable adjuvant to these measures.

1. Effect of Tonsillectomy on the Recurrence of Acute Rheumatic Fever and Chorea: A Study of Ninety-four Children.—William St. Lawrence. See MEDICAL RECORD, May 8, p. 813.

2. Industrial Epidemiology.—William Alfred Sawyer discusses certain practical problems concerning industrial epidemiology, which he defines as that phase of medicine which seeks to improve the health of individual workers and prevent the transmission of disease to their fellows. He outlines a plan which he thinks would help in curtailing the large waste due to the very frequent and all too common colds and their resultant conditions. The various communicable diseases come within the range of his consideration.

3. Influenza and Hypophrenia.—Karl A. Menninger outlines two methods of study of this subject, cites eleven cases, and draws, among others, the following conclusions: Influenza as a type of acute infection, with known neurotoxic potency, gave opportunity for study of its effect in relation to hypophrenia in the recent epidemic. Inquiries addressed to superintendents of State hospitals for the feebleminded afforded seventeen replies, representing more than 16,000 patients, but were almost entirely barren of important results, owing in part possibly to the burden and pressure of duties incident to the care and alleviation of the physical disease. This negative evidence is offset by data from the cases of the Boston series and from private practice, illustrating effects of influenza on hypophrenia. The uncomplicated cases represent: (1) Hypophrenia (feeblemindedness), with aggravation of intellectual lack prominent after influenza; (2) hypophrenia with emotional sphere disturbances notably intensified after influenza; and (3) hypophrenia with volitional and conduct disorders conspicuously aggravated by influenza; to which may be added (4) a single instance of symptomatic improvement, in all spheres, but notably that of intellect, following influenza. The complicated cases represent: (5) Hypophrenia with conspicuous neurologic manifestations after influenza; (6) hypophrenia with psychotic manifestations following influenza; and (7) hypophrenia with psychopathic manifestations prominent after influenza. Generic processes illustrated as to the rôle of the influenza are comparable to those observed in the study of the psychoses associated with influenza, namely, creation, precipitation, aggravation, and amelioration. In this the relation of influenza to hypophrenia differs from that of influenza to the psychoses, since aggravation in the latter was the least frequently observed phenomenon, and in the case of hypophrenia the most frequently observed. The usual effect of influenza on the brain is not the production or precipitation of hypophrenia, and if it ever produces hypophrenia it is probably by means of a more or less obvious encephalopathy. On the other hand, of those already manifesting mental lack, certainly a few are influenced adversely by influenza, and the symptoms of hypophrenia aggravated, an aggravation which may be predominantly in the intellectual sphere, in the emotional sphere, or in the volitional sphere. Psychoses of an indeterminate type are occasionally precipitated by influenza in the feebleminded, even as in normal persons. At least occasionally, though rarely, the effect of influenza on hypophrenia may be symptomatic amelioration.

5. Effects of Hot and Cold Applications on the Superficial and Deep Temperatures.—J. J. R. Macleod states that while it is well known that the local application of heat or cold to the surface of the body is of value in the treatment of a variety of clinical conditions, no data apparently exist to show the extent to which the application causes actual change in the temperature of the underlying tissues. With the aid of the Research Committee of the Medical Services of the Department of Militia and Defence of Canada, a series of observations was undertaken to collect such data, and the interesting and definite character of the results has prompted the presentation of this brief report. The observations were conduced on rabbits. Heat or cold was applied over an area of shaved or closely clipped skin by means of an appliance called the "applicator." The technique of application of heat and cold and of measuring the temperature at the point of contact and of the tissues is described. The following types of observations were made with regard to the influence of local heat: 1. Temperature of skin of thigh on application of electric pad. With a difference in temperature of pad and skin of 12° C., the skin temperature rose about 5°, a moderately warm applicator having almost as great an effect as one that was considerably warmer. With the skin thoroughly shaved a similar relationship between the rise of skin temperature and the temperature of the applicator was not so evident. The extent of the lateral spread of the temperature change on shaved skin was found to be considerable. 2. Temperature of skin and underlying muscle of thigh on application of hot-water applicator, to overlying skin. Although the observations are insufficient to indicate the maximal depth to which locally applied heat may penetrate the tissues, they show at least that this is considerable (over 20 mm.). The rise in the muscles is more gradual than under the skin. The heat of a poultice or of fomentations must therefore penetrate for a considerable distance, even into relatively vascular tissues. 3. Temperature in various regions of the abdomen on the application of heat to the abdominal wall. The results in general show that when heat which is about 15° C. above that of the body is applied over approximately one-fourth of the surface of the abdomen a change in temperature may occur which may penetrate the abdominal viscera for a distance of about 75 mm., although it can spread laterally only for somewhat less than 20 mm. Observations on the effects of cold gave results equally as definite as those for heat, the temperature change, of course, being in the opposite direction.

6. The Complement-Fixation Test in Pulmonary Tuberculosis: Its Use as a Means of Diagnosis.—A. L. Punch, in this preliminary report to the Medical Research Council, states that the object of the investigation was to see if it were possible by modifications of the test to obtain results of sufficient reliability to warrant its being regarded as a specific reaction for the diagnosis of *active* tuberculosis. The conclusions drawn from the results are: (1) That in the complement-fixation test we have a specfic means of diagnosis of the presence of an active or recently active tuberculous lesion. (2) That a negative reaction is as reliable an indication of the absence of such a lesion as a positive reaction is of its presence. (3) That a positive reaction in the highest dilution of complement is just as reliable an indication of the presence of such a lesion as a positive reaction in all three dilutions.

2. Discussions on the End-Results of Injuries to the Peripheral Nerves Treated by Operation.—Sir William Thorburn, after reviewing the results of various surgeons, stated that, after many years, he could only say that if a surgeon obtains 50 per cent. of really good economic recoveries after secondary nerve suture, he is doing well; if he obtains 75 per cent. of such recoveries which will bear investigation, his work is both brilliant and fortunate. On the other hand, he said not one word of death rates and of operation risks or disasters, because under modern conditions such things are and should be for all practical purposes unknown.

3. Results of Operations for Nerve Injury at the Edinburgh War Hospital.—Maud F. Forrester-Brown, after an analysis of 643 cases of nerve injury operated on in the Edinburgh War Hospital, 552 of which were traced and 396 personally examined, was led to the conclusion that every case of nerve lesion which has not recovered spontaneously within a reasonable time should be given a chance by operation, since regeneration of nerve fibers after suture can be looked for with confidence in the majority of cases, although progress must be expected to be slow. Whether recovery will ultimately be complete in the majority of cases it is too early yet to say, and the prognosis of any individual case is very hard to estimate.

4. Late Results of Operation.—J. L. Joyce confined his remarks to the late results of operations designed to bridge a gap in a nerve which cannot be repaired by end-to-end union. When one remembers the delicacy of an axon, our relative ignorance of their minute anatomical distribution, and the difficulties which must beset their transport across a gap in a nerve, the fact that the results are not good is not surprising. Rather is it to be wondered at that any recovery takes place at all; but that such does occur encourages him in the belief that the operations of pedicled autogenous transplants and of free autogenous transplants are deserving of further study and research, and still have a place in the operative surgery of injured nerves.

1. Pneumonia Patients—And How They May Be Saved.—William Henry Porter holds that the successful treatment of pneumonia is a fairly simple procedure, but must be carried out along scientific rather than sentimental lines. In pneumonia, more than any other disease, the battle is won or lost by what is or is not done during the first forty-eight hours of the pathological process.

Le Progrès Médical.

July 31, 1920, xlviii, 31.

The Grand Dyspeptic Syndromes.—Ramond regards this subject as more or less neglected. First he isolates the vasomotor type characterized by bloating immediately after a repast. It is not a true dyspepsia, but a syndrome of a subjective character which may subside in a short time or persist, according as it is accompanied or not by spasms of the pylorus. It is called forth by substances which excite gastric secretion as well as by overeating, and the author could provoke it in one subject by giving a capsule of peptone alone. The bloating is usually accompanied by flushing of the face, drowsiness, heaviness of the head, amounting at times to a headache. Sometimes the subject falls into a distressed sleep. The dilated pupils give the eyes a bright look, the conjunctivæ are congested, the nose oily, while vertigo and tinnitus aurium seem to show that the congestion involves the ears. The hands tend to become livid, cool, marbled and damp. Cardiac symptoms are mostly absent, although there is a feeling of want of air. There is a marked sense of fatigue. In the syndrome thus sketched there is no disturbance of gastric chemism and treatment is unsatisfactory. The subject must learn to abstain from articles which contribute to the attacks. Belladonna may give some relief and warm hydrotherapy is also mentioned. Other syndromes comprise the early painful and the late painful or pyloric. In the former there is also a sense of tension, but it is accompanied by pain, waterbrash, heartburn, etc. Belching is not part of the syndrome, for escape of gas would relieve the tension and no syndrome would develop. During the war the fact of swallowing the poison gas led to many similar cases, and in at least part of the cases gastritis is present, but congestion and mere disturbance of innervation suffice in others. The late painful or pyloric type is associated with some lesion of the pylorus, usually a localized gastritis, and spasmodic closure, with more or less dilatation of the stomach. The author does not mention duodenal ulcer in this connection.

Le Progrès Médical.

August 28, 1920, xlviii, 35.

The Dubreuil-Chambardel Syndrome.—Feil thus designates a form of precocious caries of the upper incisors. The physician of that name, a disciple of Professor Ledouble of Tours, published the original memoir on this subject in 1919 before the Congress of Stomatology. In this paper he reported 44 cases. The affection is one of adolescence, occurring between the ages of fourteen and nineteen. All four upper incisors are attacked simultaneously with caries, the remainder of the dentures remaining quite intact. But sooner or later, perhaps after an attack of stomatitis, the remaining teeth are involved. The interval between the first symptoms of incisor caries and total necrosis of the same is four or five years. The teeth show no vices of development or implantation and there is at first sight nothing to explain the malady. The first cases seen by Feil occurred in mother and child, showing an hereditary element. The child, aged fourten, was the patient and examination of the mother showed that she had undergone the same experience. Another patient was twenty-two when seen, but his caries had begun at the age of thirteen. Thus far nothing has been said of the syndrome. The original discoverer noted the coincidence of ogival palate and harelip in some degree. Usually an operation scar is in evidence when first seen. He has also noted a persistence of the intermaxillary bone and an infantile arrangement of the local blood vessels which appear to stand more or less in a causal relation to the syndrome.

Schweizerische medizinische Wochenschrift.

August 5, 1920, l, 32.

Chemotherapy of Influenza.—Ryser contributes an article with this title, but the term seems ill chosen, for it should be restricted to drugs able to destroy the microscopic cause of the disease, and this is not even known, so that we cannot affirm that a sterilization is possible, much less that one has been effected. The author, however, may mean the term in the sense suggested, for he speaks of having aborted cases with it, and if we concede that the disease is due to Pfeiffer's bacillus (like the author), we can understand his contention that sodium salicylate destroys or paralyzes the activities of this organism. He believes in pushing the salicylate of sodium, and since this has some depressant action on the heart, he combines it with digalen and caffeine. He criticises the use of aspirin, but combines dionine, codeine, or morphine if there is much cough. He gives as much as ten grams of sali-

cylate in twenty-four hours to robust men, and not less than six grams to women. He breaks up the daily dose in small and fractional quantities, so that at the end of the first day the subject has incorporated the entire amount —in reality this has occurred after about eleven hours. He expects to cause mild salicylism and does not mention the development of delusions or delirium said to follow large doses in certain subjects. In nonpneumonic cases the results were surprisingly good, and the author treated a large material in 1918, 1919, and 1920. Of 98 pneumonias in the first pandemic he lost but 13.3 per cent., and in the entire material less than 3 per cent. The dead succumbed to severest sepsis. Considering the deadliness of the pandemic in Switzerland, the low death rate is attributed by the author entirely to the massive exhibition of salicylate of sodium. This treatment is very similar to that advocated by Dr. Beverley Robinson of New York City, who claims to have had excellent results therefrom.

Schweizerische medizinische Wochenschrift.

September 2, 1920, i, 36.

Is Ordinary Aphthous Stomatitis a Form of Foot and Mouth Disease?—Margulis calls attention to the name "epizootic apthae," used to designate foot and mouth disease in man, and this name may suggest a possible sporadic incidence in a mild and noncontagious form. The epidemic incidence in association with an epizootic is due to the consumption of infected dairy products and infected raw meat. Now and then milkers and slaughterers may be directly infected. Transmission to mankind has been known since 1764, but not until more than a century had elapsed did the profession consider this fact seriously. It has been the custom in diagnosis of this disease to exclude ordinary aphthae. The lack of a microscopic criterion has, of course, been a great drawback in the joint study of simple and epizootic aphthae. The author recently treated a bad case of aphthous fever or stomatitis of unknown origin in a girl of fifteen. Mercurialism could be excluded, as could all other known stomatitides. There was foot and mouth disease in the next farm and the animals showed the same type of stomatitis. Despite the close proximity all evidence of a direct or mediate transmission was negative. Had there been no knowledge of cases in the dairy animals the case, of course, would have been termed stomatitis of unknown origin. This again suggests that any case of sporadic aphthae may have been exposed through dairy products or otherwise to genuine epizootic stomatitis, or that man and animals may derive the infection from a common source. In practice, however, the unusual severity of the author's case and the ability to exclude other forms of stomatitis should certainly have led to a presumption of foot and mouth disease on general principles.

Il Policlinico.

August 9, 1920, xxvii, 32.

Should Cancer of the Stomach Be Subjected to Operation?—Cavazzani answers this query in the affirmative, being actuated largely by the results published from the Mayo Clinic. He reports five cases from his private hospital as follows: The first patient had an ulcerated cancer of the stomach in which perforation developed spontaneously with secondary peritonitis. It was necessary to intervene and the author resected the pylorus. The cancer mass was very large, but was still technically operable. The intervention occurred on October 4, 1919, and was successful in every way. The tumor mass was found to be the seat of an ulcer 9 cm. across, with involvement of the regional lymphnodes and numerous adhesions. The second patient had cancer of the greater curvature, and was first seen in May, 1918. The tumor in the epigastrium was palpable like the previous case and "as large as a kidney." The woman was cachetic and her cancer had been pronounced inoperable in 1917. The author could find no absolute evidence of inoperability and performed a gastrectomy by Billroth's second method. This was successful and patient was discharged in good condition. The third subject had severe symptoms of gastric cancer and was cachetic, but the author could find no suggestion of inoperability. The woman was discharged in good condition ten days after the resection of the pylorus. The two other operations were of the same sort, ending in operative recovery. Of the five patients one is alive and well after two years, but the others had only a limited survival. One had metastases of the liver at the time of intervention. The four cases all ended fatally with metastases after a period of relief, with the exception indicated. In other words, in five cases there was no operative death and 20 per cent. of survival to the third year.

La Presse Médicale.

August 21, 1920, xxviii, 59.

Is Rickets a Deficiency Disease?—Nathan anticipates by the statement that while rachitis seems to be a deficiency disease proofs have not been forthcoming. According to the vitamine theory the disease is the result of deprivation of the lipo-soluble vitamines; but so simple an explanation is discarded by authorities. The author has been experimenting on young dogs by withholding this species of vitamine. As controls served other puppies fed on food in which fat-soluble vitamines abounded, as whole milk, cream, and butter, and cod-liver oil. Another set of animals received water-soluble vitamines only. The results showed that the fat-soluble vitamine is antagonistic to rickets. Geographical pathology seems to bear out laboratory results. Among certain very poor people in tenements of large cities Jews show much immunity based on extensive use of oil in the diet, and in communities where cattle raising is the principal industry the disease is unknown. But Hess and Unger are only partly satisfied with this view because rachitic children may be robust and in general do not behave as if they were being deprived of anything essential to life. The author does not accept this definition of a deficiency disease and this point seems the crux of the debate, which the future must clarify. The public and largely the profession have always looked on a rachitic child as substandard, especially in its earlier years. Numerous functional disturbances are said to accompany the bone disease and the subject is more prone to suffer from the infectious diseases of childhood. But in later years these children may become robust adults, bearing only certain stigmata of the disease.

Journal de Médecine de Bordeaux.

September 10, 1920, xci, 17.

Case of Pluriglandular Insufficiency.—Caussimon describes the following case: Patient was a single woman a "stenodactylographe" (or combination stenographer and typist). For two months she had complained of vertigo and palpitation, which caused her to seek treatment. At the age of twenty-four she had had amenorrhea for eight months, and afterward menstruated not over once a year. At twenty-seven evidences of acromegaly appeared. The enlargement of the fingers interfered with her occupation. Thus far the symptoms pointed to the pituitary and ovaries, but later profound asthenia set in. There was nothing in her ancestry or early history to account for these disturbances. Examined in the clinic there were evidences of both acromegaly and hypothyroidism of somewhat atypical character. The skin and hair and the mental state suggested myxedema and there was abundant evidence of acromegaly. The sella turcica showed no abnormality, but the coincidence of acromegaly with apparently intact hypophysis is not unknown. The eyes were intact and the blood count was not that commonly seen in acromegaly. The thyroid was atrophic and symptoms of hypothyroidism are not usually encountered in acromegaly. There was no evidence of persistent thymus. The early amenorrhea showed apparently that the ovary had been primarily involved. The extreme prostration evidently had no connection with hypoadrenia, but must be attributed to myxedema. Before trying polyvalent extracts the patient was given thyroid extract with remarkable results. Menstruation was resumed normally and the enlarged tongue of acromegaly coincidently became smaller.

AMERICAN ASSOCIATION OF OBSTETRICIANS, GYNECOLOGISTS, AND ABDOMINAL SURGEONS.

Thirty-third Annual Meeting, Held at Atlantic City, N. J., September 20, 21, and 22, 1920.

THE PRESIDENT, DR. GEORGE W. CRILE, IN THE CHAIR.

Some Interesting Surgical Conditions of the Liver and Biliary Tract.—Dr. JOSEPH H. BRANHAM of Baltimore said that a healthy gall-bladder should never be removed, nor should it be subjected to operation. When symptoms were severe enough to warrant operation, in most cases the organ was so diseased as to be of little or no value and was a menace to future health. For several years he had made the removal of the gall-bladder by a method that was almost subperitoneal. After the abdomen was opened the ducts and neighboring organs were carefully examined. This could usually be done by palpation. If the disease was confined to the gall-bladder, an oval incision was made over the lower anterior surface of the organ; the peritoneal coat was dissected from the deeper tissues; when the duct was reached it could always be known by the well-marked sphincter. A considerable margin of peritoneal coat was left at the liver attachment; the duct was severed, and after being explored and emptied of stones, a large catheter was fastened to it by a twenty-day catgut suture; the peritoneal coat from each side was stitched together, and then to the ventral peritoneum. This left the catheter outside the peritoneal cavity and gave a smooth serous surface over the entire wound, thus preventing adhesions. By confining the incision to the accessible part of the organ, the suturing was made easier. A small cigarette drain left in for one or two days was all that was needed in most cases. After operations were done in this way, there were few adhesions, and the patients were left usually in good condition.

Dr. ORANGE G. PFAFF of Indianapolis stated that we all aimed to be conservative in the treatment of gall-bladder diseases, but in the last few years the statement had been made that a gall-bladder once diseased, always diseased, but this was not always the case. If the abdomen was opened on account of symptoms and no stones were found, and very little demonstrable pathology, if we found a gall-bladder that was not easily emptied by pressure, such a gall-bladder ought to be drained, but in most instances, instead of draining the gall-bladder that was grossly diseased, all were now agreed that the thing to do was to remove it.

Where the Rubber Glove Is Behind the Times.—Dr. ROBERT T. MORRIS of New York City said that the rubber glove represented one of the best advances of surgery in general. It interfered with the sense of touch in some kinds of work. In abdominal work the rubber glove was not necessary if the hands of the operator were otherwise well prepared. It required a longer incision, and consequently was not in accordance with the principles of the Fourth Era of Surgery.

Dr. HERMAN E. HAYD of Buffalo, N. Y., thought that Dr. Morris did the profession a good service when he taught them to do surgery through small incisions and to develop tactile sense. He was rather surprised that a man with a judicial mind like Dr. Morris should have put before the association so strongly the results of the work of Kennedy without the use of rubber gloves. It was hard for him to believe that 99 per cent. of the cases that other surgeons operated upon who wore gloves had adhesions, while those operators who did not wear gloves had only 7 per cent. adhesions. To him this was ridiculous. Out of 100 cases, probably 60 to 75 per cent. were the simplest kind of operations and would not have taken but a short time to accomplish. He did not believe it was possible that such results could take place in the hands of 99 men with adhesions and Dr. Kennedy had only 7 per cent. adhesions from operating without gloves.

Dr. CHARLES L. BONIFIELD of Cincinnati could not believe that the rubber glove in and of itself caused adhesions. He could conceive of a man with rubber gloves on being rough, and a man without rubber gloves scratching tissues with his finger nails. One thing that induced him at an early age to wear rubber gloves was the fact that his finger nails were very hard to keep clean, and he seldom knew whether he had them clean or not, and he felt it was better to cover them up with something that he could boil. While rubber gloves might impair tactile sense a little, still they should be used in operating.

Dr. GORDON K. DICKINSON of Jersey City stated that Dr. Morris wanted to standardize operating by cutting out gloves. Why did we use gloves? Because we got infection. Why did we have infection? If one went the rounds of the clinics one would see the most incongruous things perpetrated, such as putting on soap and washing it off again. If one wanted to get his hands free from germs he must not wash the soap off and must not scrape it off. It did not do any good. Put soap on, rub it in, and one would kill the germs, and there was no germicide more potent than potassium soap.

Dr. JOHN W. KEEFE of Providence, R. I., said that a surgeon's tactile sense was not as acute with a rubber glove on as it was without it. When rubber gloves first came into use he used them in most all cases he operated on. Now and then he slipped the rubber gloves off because he thought he could feel better without them. At one time he was in the habit of going to see Dr. McBurney, who was one of the greatest surgeons America had ever produced. He told him about his difficulty, and he said that was exactly where the mistake was made. The rubber gloves should be kept on in a difficult case and the fingers ought to be educated as to how differently things felt with the gloves on. He went home and had practiced that ever since.

Dr. JAMES N. WEST of New York City stated the essayist spoke of the great tendency to standardization, with the result that it stifled originality. There were times when the surgeon could operate to greater advantage without the use of gloves than with them, particularly if he was very careful in the preparation of his hands.

Dr. ABRAHAM J. RONGY of New York City said in a large city like New York it was not only unsafe to operate without gloves, but unsafe to examine patients in the office without gloves, and as a measure of protection the use of gloves was one of the best things for the physician.

Rupture of the Bladder During Labor.—Dr. JOHN W. POUCHER of Poughkeepsie, N. Y., reported a case, stating that rupture of the bladder during labor was very rare. It might be caused by instrumentation or spontaneously by overdistended bladder. The immediate symptoms simulated those of rupture of the uterus. It was important that the bladder be frequently emptied during severe and protracted labor. Recovery of the patient depended on prompt operative treatment.

My Method of Performing Version.—Dr. IRVING W. POTTER of Buffalo, N. Y., stated that for the year ending August 31, 1920, he had personally delivered 1113 women, 920 of whom were delivered by version. Of the 920 versions, 400 were primiparæ, and 520 were multiparæ. He showed lantern slides demonstrating his method of performing podalic version. He emphasized the importance of proper preparation of the patient for delivery, the condition of the bladder, cervix and vaginal canal. He laid stress on the position of the patient during delivery, and the degree of anesthesia necessary.

Dermoid Cysts of the Ovary; Etiology, Diagnosis, and Treatment.—Dr. BENJAMIN R. MCCLELLAN of Zenia, Ohio, gave a brief review of dermoid cysts of the ovary, saying that recent research into the etiology of these strange neoplasms, especially the work of Goodall, had added new interest and emphasis to the parthenogenetic theory. As to the diagnosis, the question of possible infection and malignant potentiality in these growths demanded more careful study of all tumors arising from the pelvic basin. The *x*-ray should be more generally utilized. In the treatment the utmost care should be exercised in removing the tumor en masse, without the use of trocar or aspirator. The case reported by the author only added another example to prove the fact that these tumors did not prevent pregnancy or interfere with parturition as long as the pedicle remained untwisted.

Certain Procedures in Vaginal Surgery.—Dr. SAMUEL W. BANDLER of New York City described an operation for cystocele and prolapse of the uterus, modified by partial hysterectomy and complete perineorrhaphy. He exhibited numerous lantern slides and made a running comment on the same.

Case of Congenital Absence of the Vagina with Other Abnormalities.—Dr. DAVID HADDEN of Oakland, Cal., reported the case of a girl of 18 with absence of menstruation. The symptoms were indefinite. Examination showed external parts normal with unperforated hymen. A body felt through the rectum occupied the position of the uterus. Operation revealed the absence of a vaginal canal, the pelvic mass being the right kidney fixed in position. The cecum and appendix were undescended and located in the right kidney fossa. A general consideration of the factors involved was discussed.

Luteum Extract.—Dr. ADAM P. LEIGHTON, JR., of Portland, Maine, spoke of the necessity for combining thyroid extract with luteum in many cases. He spoke of the use of these extracts in cases of menorrhagia, dysmenorrhea, functional amenorrhea and obesity. The climacteric symptoms and others were due to ovarian insufficiency. He pointed out the great necessity for prolonged administration of luteum extract in order to obtain results.

Submucous Adenomyomata.—Dr. OTTO H. SCHWARZ of St. Louis stated that submucous adenomyomata were comparatively rare. There were only a few cases described in the literature. The condition was primarily a localized adenomyoma in the uterine wall. These tumors were usually diffuse in character. The tendency for these growths to become submucous was quite unusual. He described a very large submucous adenomyoma, unusual in structure, with marked cystic dilatation and intracanalicular projections. A subserous tumor, described by Robert Meyer, arising from the Wolffian duct or the parovarian tubules, was mentioned. The submucous tumor in the author's own case, although identical in structure with the tumor described by Meyer, was definitely of Muellerian origin.

Endocrine Influence, Mental and Physical, in Women.—Dr. JAMES E. KING of Buffalo, N. Y., pointed out that the endocrine system supplied stimulus for the fulfillment of the two fundamental laws of nature. The secretions prompted in the human being many mental attributes. In women, both the physical and mental phenomena associated with reproduction were the result of glandular secretion. There was some fact and much theory bearing on this. Woman would be better understood when we had further knowledge of the complicated operation of her endocrine system.

Case Reports.—Dr. GEORGE VAN AMBER BROWN of Detroit reported (1) papilloma of the bladder in a woman, 45 years of age; (2) a case of advanced carcinoma of the uterus in a woman of 38; (3) hydrosarcoma, mucocellulare carcinomatodes (Krukenburg type of tumor) in a woman, 57 years of age; (4) chorioepithelioma malignum with multiple fibroid tumors in uterine tissue in a woman, 35 years of age; (5) lymphoblastoma primary in the parovarium of a child 5 years of age.

Accidental Hemorrhage; Cesarean Section; Hematuria in Pregnancy.—Dr. JAMES K. QUIGLEY of Rochester, N. Y., reported two cases, one of accidental hemorrhage in which a cesarean section was done. The interesting points in this case were: (1) of the several causes advanced as factors in the etiology of accidental hemorrhage, this patient presented three, viz; trauma, a marked pregnancy toxemia, and a short umbilical cord (17 cm.); (2) extreme intrauterine pressure; (3) gross appearance of the uterus in situ, corresponding to that described by Wing and by the author in a previous publication; (4) relatively large amount of free peritoneal fluid; (5) leukocytosis and clinical improvement following the two tranfusions.

The second case was one of hematuria in pregnancy in a woman, aged 30, primipara. Of the various causes offered for hematuria and for hematuria in pregnancy in particular, it seemed to the writer that the most plausible etiological factor in this case was toxemia of pregnancy, as evidenced by increased blood pressure and edema.

Hernia of the Ileum Through a Rent in the Mesentery.—Dr. WILLIAM EDGAR DARNALL of Atlantic City, reported the case of Mrs. D., aged 46, married, one child, weight 200 pounds. She had never been seriously sick. Family history was negative. She was well developed with splendid physique and the picture of health. She had had no symptoms until recently when she noticed a "lump" in the abdomen and suffered with menorrhagia. Examination revealed a fibroid tumor of some size freely movable and uncomplicated and there was a very slight laceration of the cervix. On July 18, 1918, a supravaginal hysterectomy was done by him. From this she made a most perfect and smooth recovery and was in due time sent home. On August 12, a month afterward she ate a large dinner. The next morning about 6 o'clock she was seized with a most agonizing pain in the epigastrium and vomited. The pain was so severe that morphin was administered. Her bowels were irrigated producing a copious stool. The next day her pains were considerably improved but distension appeared. During the afternoon there was an absence of peristaltic sounds on auscultation, her pulse was increasing in rapidity and her temperature had risen to 101° F. Dr. Hobart A. Hare, of Philadelphia, saw her with the speaker in consultation and was of the opinion that in spite of the temperature there was some form of obstruction, although enemas still brought away some feces and gas. Operation was decided upon and performed at 5 P.M. The findings were as follows: Through an opening in the mesentery of the second convolution of the ileum there had slipped a loop of the ileum belonging to the first convolution high up on the left side under the spleen. There was a volvulus of this loop and it was gangrenous and perforated. There was an abscess in the left kidney pouch and foci of pus at various locations in the upper abdomen. The whole abdominal cavity was filled with fluid and intestinal contents. The hernia was released and the rent in the mesentery closed. Twelve inches of ileum was resected and a Murphy button used for anastomosis. Drainage and counterdrainage was used. Proctoclysis with Locke-Ringer solution instituted Fowler position ordered. An opportunity was afforded of inspecting the lower abdomen and pelvis which were found in perfect condition with no adhesions or constricting bands anywhere. Indeed it was rather exceptional to find everything so smooth and free from adhesions of any sort just a month after her first operation. He was unable to account for the rent in the mesentery so far away from the site of the pelvic operation, which made this unusual hernia possible. She had led a very quiet and well ordered life since her first operation and seemed in perfect health. The patient succumbed to shock in about five hours.

An Unusual Abdominal Cyst.—Dr. ORANGE G. PFAFF of Indianapolis on March 20, of this year was consulted by a young married woman on account of a large abdominal cyst which had been tapped ten days previously, twelve quarts of thin fluid having been drawn off at that time according to the statements of the patient and her husband. Her history had been one of good health. The first menstruation occurred at the age of fourteen and this function had always been normal. She had passed through three normal pregnancies, the last one three years ago, which was followed by phlebitis affecting both legs. This had, however, practically disappeared when he first saw her. She had noticed some abdominal swelling about four months before she came to him. This had not given her very much trouble until about six months before she consulted him when she began to suffer severely from pressure. Her appetite was also impaired and she had lost a few pounds in weight in that time. The abdomen was greatly distended and fluctuation was readily elicited in every part. Dullness on percussion was general with the exception of a slight indistinct resonance at the epigastrium. The case was considered one of large ovarian cyst, and on March 22, she came into the hospital and he operated on her the following day. Through the usual median incision he came directly upon the sac, which was so densely adherent to the parietal peritoneum that it required some care to develop a line of cleavage, the further separation, however, being accomplished with only moderate difficulty and he was then able to pass his hand freely in every direction, widely on either side

and almost from the diaphragm to the pelvic brim. Retracting the lower angle of the abdominal incision the bladder came into view and appeared to be normal and was free from adhesions. Its wholesome color contrasted strongly with the dark, purplish red of the cyst wall, which was firmly adherent across the brim of the pelvis, in front of the uterus on a line corresponding to the vesico-uterine fold. Upon separating the sac along this line a gush of several quarts of water occurred. He continued the separation and lifted up a flap of the material constituting the anterior wall of the cyst, which was now recognized as a perverted and greatly thickened omentum being in places more than half an inch thick. With the lower omental flap held up he came upon a number of peritoneal cysts varying in size from that of a walnut to a large grape-fruit which filled up the pelvis on both sides. The intestines were held down and away from the anterior abdominal wall by innumerable strands of adhesions, so that even when distended by gas there would be no note of tympany elicited on percussion. This was one of the puzzling elements in diagnosis. The laboratory report on the specimen removed for examination stated the condition to be one of proliferating tuberculosis with much newly formed fibrous tissues. The case which he reported was unique in his experience. The great thickening of the omentum, the extensive fibrinous formation and the restrained viscera were unusual and the resultant absence of tympany regardless of posture constituted a complex which was very puzzling indeed and very misleading in diagnosis.

Obstruction of the Superior Mesenteric Vessels from Bands, with Threatened Gangrene of the Greater Part of the Small Intestine; Recovery.—Dr. JAMES N. WEST of New York City stated that cases of gangrene of the small intestine, due to thrombosis of the superior mesenteric vessels, might have been cases of this kind. The distribution and anastomosis of the superior mesenteric vessels was such that, if they were destroyed, death must necessarily ensue. The patient, female, aged 20, had general abdominal pain for three days, then she suddenly developed violent and uncontrollable pain with elevation of temperature, increase of pulse rate, and moderate distention. Abdominal section revealed the small intestinal tract in a state approaching gangrene and a firm band, which proved to be a cecal mesentery, extending across the superior mesenteric vessels. In the inflammatory process of the appendix the cecal mesentery undoubtedly became tightly constricted across the superior mesenteric vessels, obstructing them completely, and resulting in a swelling, edema, and bloody effusion in the mesentery of the small intestines. Appendectomy was performed. The abdomen was closed without drainage. Protracted recovery ensued. Union was by first intention. Collapse on the second and third days was successfully combatted by intravenous saline infusions with adrenalin. Mild septic temperature on the fourth day. On the sixth day there was diarrhea, continuing violently until the sixteenth day. Malpositions of the cecum were frequent, and might be hypo-descent and hyper-descent. In hyper-descent volvulus of the cecum was favored and at times necessitated operation. The collapse, diarrhea, and septic temperature were probably due to autolysis. The chief lesson in this case was that when, on opening the abdomen, one found a small intestine in a state approximating gangrene, the abdomen should not be closed without careful search for the cause.

The Toxic Thyroid; Its Treatment by Ether-Oil-Colonic Anesthesia.—Dr. GORDON K. DICKINSON of Jersey City said that mental stress required a strong thyroid, adrenal, and liver. One or more might fail and produce symptoms. To handle such a case skilfully required a careful surgeon and an adept at applied psychology. Excessive action of thyroid was always associated with an overactivity of adrenal and glycogenic function of liver, and a mental state analogous to fright. Surgery of the thyroid under these conditions demanded recognition of component states. A slight affront to the mind overreacted on thyroid and adrenal. Proper technique demanded elimination of such possibility. Anesthesia cone to the face and surgeon working at the neck were mental traumatisms. In ether-oil-colonic anesthesia we had the ability to anesthetize patients safely without their knowledge.

Gehrung Pessary.—Dr. EDWARD J. ILL of Newark, N. J., drew attention to the value of the Gehrung pessary. In Vol. 13, page 513, 1880 of the *American Journal of Obstetrics and Diseases of Women*, Dr. Eugene C. Gehrung of St. Louis wrote an article on the mechanical treatment of cystocele. He urged the use of the pessary in those, who were old and decrepid, for those with decompensated heart disease, diabetes and extreme renal affection. Also for those with pulmonary affection that contraindicates anesthesia and lastly the timid ones. It was by no means to take the place of the Watkins operation of which he spoke in the highest terms.

Enuresis.—Dr. JOHN W. KEEFE of Providence, R. I., said that viewing the subject of enuresis broadly, he arrived at the following conclusions: (1) Considering the multiplicity of measures that have been found to assist in the cure of enuresis, it would seem that underlying them all, must be some common factor, which is a psychophysiological impression made upon the brain. (2) Heredity undoubtedly plays an important rôle. (3) These patients have a neurotic, unstable nervous system accompanied many times by mental retardation. (4) Psychotherapy, mental suggestion and education of the subconscious mind should supplement any other form of treatment to the end that we may anticipate involuntary or voluntary micturition. In a word his contention was that the cure was the result of the mental awakening and stabilizing of the brain cells that controlled the act of micturition.

Pathological Leucorrhea and Its Treatment.—Dr. FRANCIS REDER of St. Louis said that all pathology had physiology as its basis. A leucorrhea which was physiological must be differentiated from one which was pathological. To gain an exact knowledge of the condition of the genital tract it was well to take an existing leucorrhea as a starting point. The character of the discharge, and the various states upon which the discharge depended, might reveal the seat of the disorder. The term leucorrhea grouped together a large number of lesions, and although it was the most common and prominent symptom in the majority of utero-vaginal cases, the fact that certain constitutional disorders had important relations with the different forms of leucorrhea must not be overlooked. Under such conditions it was not merely the expression of a symptom, but of the disease itself. Different periods of female life presented different kinds of leucorrhea. Forms of leucorrhea which were not pathologic were easy to diagnosticate and readily yielded to proper treatment. A pathologic leucorrhea often presented great diagnostic difficulties. Its response to treatment was frequently unsatisfactory.

The Female Pelvic Ureters.—Dr. DAVID W. TOVEY of New York City said that palpation of the ureters should be a part of every vaginal examination. Ureteritis, because of the nerves irritated, might simulate disease of any of the abdominal organs. Palpation would make the diagnosis. There was nothing between the palpating fingers and the ureters but the anterior vaginal wall. They were marked on the anterior wall by the ureteral ridges, and could be felt from their entrance into the bladder to the pelvic brim. They were felt as flattened cords the size of a leather shoe string, and could be displaced in the loose cellular tissue. In ureteritis, periureteritis, stone, pyelitis, and tuberculosis, the ureter was thickened and tender. Ureteritis and periureteritis were commonly due to infection from the cervix, and it might follow hysterectomy. It was a condition often mistaken for cystitis. Palpation showed a thickened tender ureter with intense desire to urinate. Treatment should be applied to the cervix and parametrium and not to the bladder, as cystoscopic examination showed the bladder to be normal.

Pseudocholecystitis.—Dr. HAROLD D. MEEKER of New York City drew the following conclusions: (1) The occurrence of adventitious bands in the upper abdomen has been established beyond question. (2) These bands give rise to definite symptoms. (3) The gall-bladder is the viscus most frequently involved; the resulting symptoms simulate a cholecystitis. (4) Plastic surgery has given definite relief. As complete freedom from symptoms has been recorded ten years after

operation, it is reasonable to suppose relief may be permanent. (5) It is illogical and unfair to patients to withhold a chance of relief because the origin of these bands may not yet have been definitely established. (6) The frequency with which adventitious bands in other parts of the abdomen coexist with those of the upper abdomen, emphasizes the importance of a thorough search of the entire gastrointestinal tract for abnormal bands and fixed points. (7) It is to be hoped that a comprehensive discussion of these bands will be found in the surgical textbooks of the near future. A knowledge of the condition will be the means of restoring to a life of comfort many individuals otherwise condemned to continued suffering.

Double-Flap Low Cesarean Section Results.—Dr. THURSTON SCOTT WELTON of Brooklyn, N. Y., stated that as a result of the findings in this series of a total of 55 cases he had concluded as follows: (1) The double flaps and low incision offer great protection against extension of infection to the peritoneum from an infected uterus. (2 As a result this should be the operation of choice in all potentially infected cases. (3) This fact, also, should extend the field for cesarean section to include such cases as have been long in labor with the membranes ruptured and potentially infected from frequent vaginal manipulation in which most men would elect to do a craniotomy on a living child rather than do a classical section. (4) The double flaps, likewise, so completely peritonealize the uterine wound that adhesions and post-operative disturbances are greatly minimized. (5) From the results obtained and the reasons given, the two flap low cesarean section should be the operation of choice even in elective cases.

Pyelitis in Pregnancy, with Report of Cases.—Dr. GREER BAUGHMAN of Richmond, Va., reported three cases of pyelitis complicating pregnancy. He showed lantern slides and charts and pyelograms indicating the progress of the cases. All of the cases were treated with pelvic lavage. Living babies were born to the two patients upon whom labor was induced at a selected time, while in the case of the patient who entered labor before the time set for the induction of labor, the child died. With the exception of a few treatments the patients after the first reaction showed marked improvement in symptoms. In all of the cases the right pelvis was primarily involved. In two the bladder was early involved, in the other the bladder signs were not prominent. Bacillus coli was the exciting cause of two; staphylococcus albus of the other. In all of the cases the curve representing the right and left pelvic sizes were parallel. A most marked improvement was noted in all symptoms, pelvic size, and urinary findings following delivery, showing that the obstruction did take place from the uterus and its contents. It was found possible to irrigate all of these cases within two weeks after the time of their delivery. None of the cases had any rise of temperature during the puerperium.

Borderline Carcinoma of the Cervix and Its Treatment.—Dr. EDWARD A. WEISS of Pittsburgh said that when a diagnosis of cancer of the cervix has been made, appropriate treatment should be given at the earliest possible moment, nevertheless haste in operating was not always advisable. He had found from practical experience that preliminary preoperative rest in bed for several days resulted in a marked diminution in the size of the diseased cervix, but more important still, there was often noticed a decidedly less thickening and fixation of the broad ligaments, proving that the fixation was inflammatory rather than malignant invasion of the lymphatics of the broad ligaments. As a result of this observation he had frequently found that the supposedly inoperable case was really operable or borderline. During the period of rest in bed, more careful study of the patient's resistance could be made and should radical treatment follow, the condition of the patient was greatly improved and offered a better operative risk. In the borderline cases, the improved Byrne cautery technic, which was practically the first stage of the Werder radical igni-extirpation, had given him the best results in many years, and while only a few so-called permanent or five years cures were obtained, yet he had had several instances of complete freedom from symptoms for periods of from three to five years. In thirty-eight borderline cases so treated, there was recurrence with death in one case at six months; two in nine months; five in twelve months; five in eighteen months; eight in two years; five in two and one-half years; two in three years; three in three and a half years; two in four years; one in five years, and four were not to be traced after the first year. In this series one death resulted on the fourth day from embolism. The results obtained by him with radium in a series of advanced or inoperable cases were so striking that a series of forty-five borderline or Group IV cases, radium instead of the cautery was used, and while the results were disappointing in some instances, he was forced to admit after taking all factors into consideration, that in a small series radium had proved to be a most valuable adjunct, both as to immediate and remote results. To say that radium used in the cervix was a harmless procedure, it was not in accordance with facts and its indiscriminate use would bring discredit on a very valuable adjunct in gynecological therapy. In using the cautery in the treatment of borderline cancer a clear distinction must be made between the so-called Percy cauterization and high amputation by the cautery. In the former the cervix was not removed, but a deep charring resulted which was often followed by fistula formation and severe constitutional reaction. The subsequent use of radium would not only be of little value, but would increase the tendency to fistula. Cancer of the cervix was still to be classed as an operative condition when discovered early and the patient a good risk. When a doubtful borderline condition was presented treatment by radium was advisable and the question of subsequent operation should be decided by the reaction obtained; but if the operation was contraindicated by age, general condition, heart, kidney, or blood vessels, radium alone should be used.

Splenic Leucemia Associated with Pregnancy.—Dr. GEORGE W. KOSMAK of New York City said that a survey of the reported cases of leucemia complicating pregnancy in which a fairly definite diagnosis from the blood picture was made, disclosed a total of 12, including 2 of the writer. The ages of the patient varied from 24 to 40, the majority being between 32 and 36. With the exception of Peterson's case all were multiparæ. A possible hereditary history was mentioned in only one case. The parity varied from three to nine. In most of the cases he got a history of living children that showed no tendency to the disease up to the time of the report, but in a few instances he was told that the babies died at varying periods after labor, from a few days to five months. In four cases mention was made of the birth of macerated or stillborn fetuses. Among these twelve cases the mother survived in but two, but how long these mothers lived was not stated, nor the subsequent course of the disease. In the majority of cases he found that the woman survived but a short time after labor. One of his patients died before delivery took place. In Peterson's case, death came on an hour after labor and in Hilbert's case ten hours, and Lauenburg's forty hours after labor. There was a record of death in Stillman's case one month after delivery, his second case died in two weeks and Jaggard's case eleven months after delivery. In every instance but one (his own case) in which the definite diagnosis was presented the splenomedullary type of the disease was observed. It would be noted that in many cases the authors mentioned a prodromal period in which progressive emaciation, anemia, and loss of strength were noted soon after a pregnancy, from which no recovery resulted, and during which period the woman again became pregnant. The leucemia itself did not therefore appear to be a deterrent factor to conception. Although the presence of a true leucemia as a complication of pregnancy was from all available records a very rare condition, nevertheless one ought to be on his guard against it. Probably a considerable number of cases of marked anemia in which no satisfactory blood count had been made might have been true instances of this disease. In many cases where an anemic patient failed to recover under proper treatment, a more minute and detailed examination of her blood should be made with reference to the possible diagnosis of leucemia. The occurrence of pregnancy in this disease indicated a most unfavorable outlook for the mother and conception must therefore not be allowed to take place where the condition was

suspected. The prognosis was undoubtedly worse in the pregnant than in the nonpregnant and whether the association was accidental or not was immaterial. Where the disease was already present abortion seemed to be the rule, with a rapidly progressing course and a fatal issue. The presence of an enlarged spleen was an almost constant factor in the disease and should lead one to look for this sign in every anemic patient. The value of the *x*-rays in leucemia had been brought forward but in the event of a pregnancy its application, as a cure for the disease might work an undoubted harm on the fetus and the induction of labor should be done before radiation was begun. It was necessary to distinguish between the acute and chronic forms of leucemia. Pregnant women might contract a rapidly fatal leucemia if the evidence of the cases thus far reported was to be believed, although it seemed possible that the disease was present in a milder form in many of these patients before their last and usually fatal pregnancy occurred. It would be noted that there were apparently cases of chronic leucemia in this series in which pregnancy and labor occurred, and for this reason conservative treatment had been advised under such circumstances. In view of the rapidly fatal ending during the puerperium it would appear that this advice was not justifiable and that in order to avoid such an outcome labor had better be induced in all cases.

Benign Mammary Tumors and Intestinal Toxemia.—Dr. WILLIAM SEAMAN BAINBRIDGE of New York City reported a series of 25 cases of abnormal mammary changes apparently caused by autointoxication. Each of the patients who suffered from abnormal breast conditions had, in addition to the breast changes, coexistent chronic intestinal toxemia, the mammary gland frequently registering the degree of toxic poisoning. He divided the cases roughly into three classes: (1) Patients with a condensation of lobulated induration of the upper, outer quadrant of the breasts, usually along the edge of the large pectoral muscle and where the dependent breast dragged on the upper axillary margin. These were lumpy, toxic, or stasis breasts. (2) Patients with breast changes as in Class 1 but with the added condition of localized degeneration of the mammary gland, such as adenomata or cysts. (3) Patients with breast changes as in Classes 1 or 2 and in conjunction an abnormal discharge from the nipples. The majority of the cases were patients with marked intestinal toxemia. A few had complicating pelvic condition. Cases cured with medical measures, 5; cases cured by surgical relief of the chronic intestinal stasis and without operation on the mammæ, 15; cases cured after operation for adenoma or cystoma and for the intestinal stasis, the remaining indurated, lobulated portion of the breast returning to a normal condition, 1; cases cured by the removal of an adenoma or cystoma from a toxic breast, and by preliminary and after-treatment for the intestinal toxemia, 3; and a case in which stasis breasts were removed, the underlying intestinal toxemia not being recognized, 1. The following were the author's conclusions: (1) There are definite abnormal conditions of the breast tissue due to intestinal toxemia. As the thyroid gland is changed by toxemia, so the mammary gland may be altered completely by chronic intestinal stasis. (2) Under medical treatment an appreciable number of these cases with abnormal breast conditions are cured. A proper uplifting abdominal corset applied for enteroptosis, careful diet, catharsis, breast supports for dependent organs, digestives, intestinal antiseptics and certain physiotherapeutic agents are among the corrective measures which often cause even well defined tumors of the breast to disappear. Any element which tends to diminish the gastrointestinal fermentation is of value. A preliminary lessening of the general toxic condition of the patient materially aids the surgeon in determining the true benign neoplasm and saves a considerable amount of recoverable breast tissue too often unnecessarily sacrificed. (3) Surgical procedure frequently is required for the correction of the intestinal stasis and the removal of the cystoma or the adenoma before the indurated, lobulated tissue resumes a healthy gland condition and the breast is brought back to normal. (4) When these toxic cases are seen early the beginning changes in the breast are often overlooked or, when the condition is well developed, the incorrect diagnosis of malignancy is made. One question naturally forced itself upon the profession in this connection: Would an early recognition of the toxic breast and the timely and efficient treatment of the underlying cause tend to lessen the danger of malignant degeneration of the mammary gland and thereby render unnecessary much of the mutilation of the human breast?

Some Cases of Thrombophlebitis During the Puerperium Following Influenza.—Dr. LEWIS F. SMEAD of Toledo, Ohio, said that the present interest in septic, puerperal, pelvic thrombophlebitis dated from a paper by Trendelenburg in 1902. The condition was not infrequent in the puerperium, because of the slowed blood current and the opportunities for infection. The disease consisted usually of a streptococcus infection entering, as a rule, through the placental site, extending by the ovarian and uterine veins, and resulting in pyemia and death in about 50 per cent. of the cases. The acute cases were rapidly fatal, but in the subacute ones the prognosis was better, largely because the progress of the infection was delayed or blocked by a thrombosis in the pelvic veins. Perivascular and uterine abscesses were common multiplications. The clinical course of the disease was marked by a suddenly fluctuating temperature, severe chills, a relatively low pulse rate, and a prolonged course of the disease. A sharply defined, painless, slightly tender, cord-like induration in the region of the pelvic veins could be made out sooner or later. The results of the blood cultures were uncertain. A striking feature was the surprisingly good condition of the patient between the rigors. The diagnosis of pelvic thrombophlebitis was fairly accurate. Differentiation must be made from septicemia, pelvic lmyphangitis, uterine infection, and thrombophlebitis in other vessels. The operative mortality was undoubtedly somewhat lower than the nonoperative. The indications for operation were hard to define, but cases with septicemia, metastatic foci, and vena cava involvement were not operable. Prophylaxis consisted of intelligent obstetrics, careful asepsis, complete evacuation of the uterus, and good drainage, with a minimum amount of traumatism and hemorrhage. The circulation in the puerperium was kept active by good food, fresh air, early rising, and heart stimulation if necessary. The nonsurgical treatment consisted of general supportive measures with the avoidance of anything which might dislodge a thrombus, such as douches, enemata, and pelvic examinations. Vaccine and serum treatment had been disappointing. The surgical treatment consisted in the ligation or excision of the involved veins by the transabdominal route and by the drainage of perivascular abscesses. Opinion upon the question of surgical intervention in pelvic thrombophlebitis was still divided, but all agreed that great conservatism must govern the choice of cases and the decision for operation. The report of three cases of pelvic puerperal thrombophlebitis following influenza accompanied the paper.

Fibroma of the Ovary.—Drs. EDMUND D. CLARK and WILLIAM E. GABE of Indianapolis drew the following conclusions: (1) Ovarian fibromata are sufficiently rare to warrant the report in all carefully studied cases. (2) The diagnosis is dependent solely on microscopic examination. (3) In presence of a hard, unilateral, movable tumor with ascites, where the more common causes of ascites can be ruled out, ovarian fibroma is highly probable. (4) The treatment is operation; the prognosis good. (5) The gross pathology of the condition is extremely variable; the microscopic pathology, as pointed out by Hellman, must show a certain regularity of the individual fibers or muscular cells and strands, despite varying quantities of cells, fibers, vessels, and degenerative changes.

Some Indications for Hysterectomy.—Dr. JAMES F. BALDWIN of Columbus, Ohio, said that very many women suffered from chronic uterine hyperplasia, frequently complicated with laceration of the cervix, retroversion, a tendency to procidentia, with leucorrhea, dyspareunia, sterility, backache, and general ill health. In this type of disease no treatment effected a cure, and little could be accomplished in palliation. Other women suffered from imperfect development of the uterus, with sterility, painful menstruation, and other disturbances. The paper was a plea for the radical cure of these two classes of cases by hysterectomy, but with saving of appendages so as to obviate the symp-

toms of the menopause, except as to the absence of menstruation.

The Treatment of Abortion Complicated by Sepsis.—Dr. GEORGE A. PECK of New Rochelle, N. Y., drew the following conclusions: (1) The conservative treatment of abortion complicated by sepsis is based on pathological entities and clinical end results. (2) Hemorrhage is the only symptom that may demand a prompt and thorough emptying of the uterus for its control. (3) Every intrauterine manipulation or procedure should be executed with the greatest care to avoid traumatizing and otherwise injuring the endometrium. (4) Late cases, and especially those already subjected to curettement, are eminently suitable for this form of treatment.

Missed Abortion.—Dr. JENNINGS C. LITZENBERG of Minneapolis stated that missed abortion was the retention of a dead fetus before viability retained *in utero* more than two months after birth. It was a common condition. It was dangerous. (*a*) Temporary ill health until the uterus was emptied; (*b*) permanent ill health. The diagnosis was not unusually difficult. The uterus should be emptied before the above symptoms became a menace to health and life.

The Preparation of the Skin for Operation, with Special Reference to the Use of Picric Acid.—Dr. H. W. HEWITT of Detroit said that it seemed clear that a good preparation for disinfection of the skin should possess the following properties, namely, (1) it should be simple and easy of application. (2) It should be efficient, *i.e.* it should have the power of destroying the common skin organisms in a comparatively short time (not over three minutes), and it should be sufficiently powerful to keep the skin sterile during the operation. (3) It should not macerate or injure the skin in any way. (4) In laparotomies it should not injure the peritoneal coat of the intestine, should the intestine accidentally come in contact with it. (5) It should be of universal application. (6) It should contain no proprietary preparations, since these were of unknown strength and could not be depended upon. (7) It should be standardized, so that its antiseptic value might be known. (Solutions might be standardized by the Walker-Rideal method.) Now, of all the methods and chemicals in use to-day, very few approached this standard. Bichloride of mercury in aqueous solution would not sterilize the skin; in Harrington's solution it was efficient, but Harrington's solution contained hydrochloric acid and injured the skin to a greater or less extent. The speaker had used this solution extensively and had discarded it. About three years ago his attention was attracted to picric acid as used in the British Army. Chemically, picric acid was known as trinitrophenol; it was soluble in 95 parts of water and 16 parts of alcohol. It had been used to a large extent in the treatment of burns, and was known as a parasiticide. It was also astringent, and deeply penetrated the corneous layer of the skin. Its only disadvantage had been in staining the skin, an effect which would last from twelve to eighteen days, but might be removed by the application of a 5 per cent. solution of carbonate of soda or a 25 per cent. solution of ammonia in ethyl alcohol, provided this was done immediately after the operation was finished. The picric acid solution used in these experiments and in his clinic was made by saturating a 70 per cent. ethyl alcohol solution with picric acid, which made a 6 per cent. solution. The merits of this method of preparation were many, namely, it was simple; it was cheap; it was efficient; it did not injure the skin in any way, and might be used on any part of the body; it did not injure the peritoneal coat of the intestine; it contained no proprietary preparation, and its antiseptic strength might be standardized. This was only a preliminary report. The staff of Grace Hospital, Detroit, had used this preparation, up to August 1, 1920, in 926 cases, and it was now the adopted method of skin preparation in that hospital. The number of cases reported was still too small to justify definite conclusions, but the writer hoped at some future time to report a series sufficiently large to be of clinical value.

Pathology of Common Puerperal Lesions.—Dr. JOHN OSBORN POLAK of Brooklyn, N. Y., stated that in order to thoroughly grasp the physiological pathology which actually took place, one must appreciate that the uterus was a puerperal wound during involution. Its interior was undergoing the normal process of repair and inoculation of this wound would produce either a toxemia or a definite inflammatory reaction depending largely on the character of the infecting organism. (1) At first, this wound infection was a local process which might be illustrated in the infected perineum, or the infected cervix tear, or the infected endometrium. In each there was an inflammatory reaction in the adjacent tissues, which limited extension of the infective process and confined it to a circumscribed area about the wound or within the uterus. In these localized lesions the pyrexia and other constitutional symptoms were due to two factors. The toxemia resulting from an absorption of the toxins liberated by the bacteria and second, to the tissue reaction excited. (2) On the other hand, the process might be a spreading infection extending beyond the wound area. This was due either to the increased virulence of the infecting bacterium or to the diminished resistance of the tissues. This spreading infection might occur by extension through the lymphatics within the walls of the uterus, spreading to the lymphatics in the parametrium producing a parametritis, or a peritonitis, or even a bacteriemia, or the infection might extend through the blood vessels, in which case it manifested itself clinically as a thrombophlebitis, an embolic pyemia or a bacteriemia. Clinical experience had shown him that a well contracted uterus in normal anteversion was capable of emptying itself of its contents if infection was not introduced from the outside. Experience had taught him that any sort of trauma to the delicate granulation wall of the puerperal uterus which was confining the infection within the cavity, opened avenues of extension, and that lateral parametritis was a constant sequel of attempts at digital or instrumental evacuation. It was important to note that the encapsulated germs did not always lose their virulence, but might on the occasion of subsequent traumatism or operation break out with increased virulence and cause a bacteriemia. In blood stream infections the local pathological reaction was considerable, consequently the local symptomatology was insignificant; for whether the bacteria entered the blood stream via the lymphatics, or via the veins, their transit was so rapid and the reaction caused so insignificant, that appreciable local lesions must necessarily be absent. For the entrance of bacteria into the blood stream, there must be a puerperal wound which was inoculated by bacteria. Broadly speaking, the treatment depended on the pathological diagnosis and might be considered under the following heads: 1. Local measures which secured drainage and uterine contraction. 2. General supportive measures that increased the patient's resistance. 3. Specific remedies, especially of value in blood stream infections. 4. Finally, surgical measures. These were only applicable to abscess formations and thrombotic lesions of the pelvic veins.

Some Factors That Determine Tissue Resistance to Cancer.—Dr. JAMES E. DAVIS of Detroit said that the life of a complex organism was the result of cell interactions and the internal metabolism of the individual cells. Factors altering cell interactions were tolerated by the high vertebrate forms only when it was possible to accomplish conformation within a limited period of time. Convincing examples of this fact were observed after amputations, resections, traumatizations, autotransplants, homotransplants, and heteroplastic grafts. Loeb transplanted thyroid into subcutaneous tissue, removed it seven days later, and found the transplant surrounded by a connective tissue capsule rich in fibroblasts. Inside the capsule a large vessel was proliferating. In the capsule and about the vessel a few thyroid acini in contracted form were persisting. Necrosis, hemorrhage, and organization were going on elsewhere, conforming the transplant. The transplantation of tumors in the higher species of animals had failed, excepting the infectious sarcoma of dog. In the normal tissues resistance was adequate for control and destruction of inherent neoplastic dynamic growth power which was uncontrollable in its autogenetically prepared tissue. The cell and its surrounding fluid possessed interactive and retroactive properties. The most convincing proof of this was given by Carrel who had grown connective tissue *in vitro* for almost eight years. The plasmatic jelly medium when used too long became

liquefied, its fibrin disappeared, and the air rarified, effecting a marked slowing of growth. Fresh, unused plasma from the icebox promptly quickened the growth rate. The plasma from a chicken four to five months old caused a growth fifteen microns more extensive than did that from a five to six year old fowl. The reactions following exhaustion, irritation, and specific diet gave acidity, toxicity, and cytoplasmic sensitization. Measurement of these states was a procedure of real scientific value to the clinician. The reaction of connective tissue to epithelial neoplasia before and after its invasion was significant and important. Epithelial cell disintegration stimulated phagocytic and proliferative connective tissue reaction and the latter in turn might probably cause increase of dynamic growth power, without a corresponding increase of nutrition. The clinical recognition of long continued cell irritation and unbalance of tissue was too frequently delayed until after the expression of organic functional disorder. The determination of stressed or irritated tissue potentiality should have much attention. The determination of sensitization acidity, and oxidation reactions were essentially quantitative tests which had relational value in this problem. It was mainly a quantitative difference in energy and time factors that existed between regenerating and cancerous cells and it was for this difference one should test. Physiological growth, regeneration, and neoplasia utilized the same means to produce a product and resistance was an essential cause for all three. Normal growth was production under control, regeneration was production to control, and neoplasia was production without control.

NEW YORK ACADEMY OF MEDICINE.

SECTION OF SURGERY.

Stated Meeting, Held April 2, 1920.

DR. SEWARD ERDMAN IN THE CHAIR.

Jejunal Colic Fistula Sequel to Resection Anastomosis of Transverse Colon for Carcinoma.—Dr. MARTIN W. WARE presented this patient, an elderly man who had previously been operated on by Dr. Haynes, who did a resection anastososis for carcinoma of the transverse colon. The man's chief complaint was a rapidly progressive loss of weight and flesh, notwithstanding a voracious appetite, and diarrheal movements shortly after the ingestion of food, and particularly at night. In addition there was a diastasis of the recti muscles throughout the entire abdomen. The radiograms obtained either with the bismuth contrast meal or enema did not disclose any filling defect or stricture characteristic of a recurrence of the carcinoma. On the other hand, the large intestine was conspicuously dilated in its entire continuity. In the screen and in the picture the injected bismuth was seen to pass from a loop of small intestine into the large intestine, and *vice versa*. This loop of small intestine showed the striations of the bismuth coated valvulæ conniventes by which it was indented. It was dilated, but not so much as the large intestine. The balance of the small intestinal tract was not so distinctly outlined. The ingested bismuth did not even reach the ileum sufficiently to outline its transition into the cecum. The *x*-ray located a communication between a loop of the small intestine high up with the large gut by a small ostium in the vicinity of the splenic flexure. Dr. Ware operated on the patient in August, 1919, doing a laparotomy by an incision extending the entire length of the abdomen. There was no evidence of fluid or scattered miliary deposits of carcinoma. The liver surface and substance were free of any nodules. There were no enlarged glands in the mesentery or transverse mesocolon. Some adhesions between the omentum enveloping a loop of the small intestine, identified as ileum, leading down to the cecum, was found collapsed. A loop of gut identified as jejunum, adjacent and adherent to dilated large intestine, proximal to the splenic flexure, was divided. The defect between the jejunum and the colon was closed by a purse string suture of chromic catgut reinforced by a Lembert suture. Exploration of the site of the lateral anastomosis failed to reveal any evidence thereof other than a larger extent of dilatation in the transverse colon than obtained in the rest of the extent of the colon. Even the transverse mesocolon appeared normal, and the haustra could be traced uninterruptedly over the colon. To overcome the wide diastasis of the recti, the abdomen was closed by overlapping side to side of the rectus sheath harboring the atrophied muscles. Within twenty-four hours after the operation the diarrhea so incessant by day and night ceased never to return. Primary union took place. On the fourth day a light diet was instituted, in turn followed by regular diet. On the fifth day the bowels moved by pituitrin given intravenously. By the tenth day the patient began to feel stronger, and by the time he left the hospital was able to walk unaided, having gained 5 pounds above a weight of barely 100 pounds before the operation. He had since gained 40 pounds and was in perfect health.

Dr. I. S. HAYNES said he had first seen this patient in June, 1905. At that time he gave a history that since the preceding January he had had colicky pains through the abdomen, with some tenderness in the abdomen, more pronounced in the right iliac region. He had lost 10 or 15 pounds in weight. He had had alternating constipation and diarrhea. The family physician said the man had appendicitis. When he saw the man he did not agree with that diagnosis. The man was thin, but not cachectic. An exploratory operation was performed and a typical annular carcinoma found involving the colon near the splenic flexure. A resection of the colon was done and a lateral anastomosis. The man had a stormy convalescence, but made a good recovery. More than two years after he began to complain of peculiar symptoms which terminated in the condition which Dr. Ware had found. During the meantime he had been well and had gained in weight. His weight then dropped to 131 pounds, and he said he had a peculiar feeling that his intestines were swishing around and he had many loose stools. An *x*-ray plate was made, which showed the colon normal, but when he was in the erect posture it was completely ptosed and pressed on the rectum. He had no pain at this time, but diarrhea, particularly at night. He was given symptomatic treatment and he reported that his bowels were moving once a day and five or six times at night. He then grew better and that was the last the speaker had seen of him until he came to tell him of the successful operation Dr. Ware had performed. The points of interest were that the patient had had an operation on the suspicion that he had a serious condition, though his symptoms were indefinite. An annular carcinoma was removed, and the man had remained well until the time when this peculiar fistula developed between the duodenum and the colon.

Dr. L. T. LE WALD asked Dr. Ware how frequently this condition had been observed. He said they had seen two cases of jejunal colic fistula following gastroenterostomy, in which there was a connection between the jejunum and the transverse colon and the gastroenterostomy—all having a common opening. The opaque meal passed directly through the jejunum into the colon, and by injecting the opaque mixture into the colon it passed into the stomach. He did not know how this had occurred, but it was noticed about a year after the operation. In the second case about a year elapsed after a gastrojejunostomy until the fistula was noted. The third case Dr. Le Wald said he had seen at the Mayo Clinic just a short time ago. In this instance one could easily have been confused as to whether the fistula was in the large or small intestine except for the fact that one could see the striations of the valvulae conniventes.

Cranioplasty (Two Cases) Lantern Slides.—Dr. JOSEPH E. J. KING presented two patients upon whom cranioplasty had been done. These were men who during the war had received skull wounds which had left large defects. Dr. King gave a lantern slide demonstration showing the method by which cranioplasty was performed. The incision was made in the line of the old scar, all excess of scar tissued dissected away, the bony edges freshened, and bone transplants sutured into place. An effort was made to avoid opening the dura unless it was absolutely necessary.

Dr. EDWIN G. RAMSDELL said Dr. King was to be

congratulated on his excellent results. Last November he had reported before the First District Branch of the State Society and also before the Westchester County Medical Society, a series of 254 cases of bone grafting from the Clinic of Dr. Delagenière of LeMans, France. Of these 60 were cranioplasties. The technique used might be of interest to the section because it was uniform so far as the graft was concerned, and varied somewhat from the technique of Dr. King. In all cases the graft was taken from the internal surface of the tibia with a chisel and mallet. It was about the thickness of a 10-cent piece, and was made up of periosteum to which were attached chips of bony cortex. The graft was flexible and easily molded to the convex surface of the skull, or, in the work on the maxillary defects, fitted into a deformity in the angle of the jaw or into a defect of the chin.

These grafts were used for four groups of cases: (1) Cranioplasties; (2) the maxillary fractures or other bony facial defects; (3) cases of non-union and mal-union with loss of substance of long bones; (4) in reconstruction of flail and ankylosed joints. The technique, as far as cranioplasties were concerned, was as follows: The old scar was excised, the bony defect outlined and dura exposed. The pericranium was elevated for some little distance from margin of defect, a piece of graft was cut to fit into the defect, periosteal surface toward dura, then other pieces of graft were placed over the defect, with ends inserted between the pericranium and surface of skull, bony surface of graft toward bone. No sutures were ever placed in the grafts. The pericranium was approximated as well as possible and the scalp closed with interrupted sutures. It was astonishing to note how quickly these grafts became consolidated. Within a very few weeks there was no evidence of former defect, except a scalp scar.

Dr. J. C. A. GERSTER said he had used the Delageinière grafts for defects in the angle of the lower jaw in four or five cases, and invariably obtained good union. It was surprising how quickly the callus formed.

Dr. SEWARD ERDMAN asked how long after the healing of the wound it was safe to perform grafting.

Dr. KING replied that it was not safe to do a grafting operation in these cases under five months. In 78 cranioplasties they had had two failures and those were due to sepsis. These two cases were operated on a little under three months after the injury was received. Those grafts had to be removed. The rest all stayed in place and healed very nicely.

Extensive Carcinoma of Both Breasts with Metastases.—Dr. JAMES BURTON LEE presented this patient, a woman 64 years of age, who had had tumor of the breast for twenty-two years. It first started as a small pea-like body above the nipple in the right breast. The tumor had grown and spread until it involved both breasts and the chest wall. It had been ulcerated for the last twelve years. The woman had a mass in the supraclavicular region, in the head, and in the abdominal wall. There was also a metastasis in the arm. It was a typical scirrhous carcinoma which had been suppurating for twelve years. It was, of course, inoperable, and the only thing that was done was to keep it as clean as possible. The woman had lost weight but was not suffering to any great extent from the condition.

Results of Surgical Treatment of Carcinoma of the Breast.—Dr. BURTON JAMES LEE and Dr. L. B. KINGERY presented this paper, which was read by Dr. Lee. (To be published later.)

Dr. EDWARD WALLACE LEE said the case that Dr. Lee had presented was interesting in one respect, and that was that in traveling in rural districts, away from civilization, one would find a good many of these cases. In one district, especially in New York State, he had talked to the local doctors about these cases, and asked what they did with them. He was told that a certain old lady had had a cancer for fifteen years. In the summer they treated themselves with plantain leaves and in the winter with mutton tallow. Dr. Lee said he had been watching these cases of breast cancer for forty years, and he would like to live to be one hundred, for possibly by that time he might learn when to operate and when not to operate for cancer. He cited the case of a woman whom he saw three months ago. She had had a cancer for five years. He removed the breast and the axillary glands and gave her *x*-ray treatment before and after the operation. She had $80,000 worth of radium applied for sixteen hours, thinking that would fortify her. After operation she had electric coagulation treatment, and yet he had never known a case to progress more rapidly than that one did. The woman was dead within three weeks. Dr. Lee mentioned a recurrence after sixteen years. Was that a recurrence or was it a new cancer?

Dr. JOHN F. ERDMANN said he had brought a set of *x*-ray plates to show in connection with Dr. Lee's paper, thinking they might be of interest to the members of the Section. These plates were taken from a patient operated upon when the woman was 41 years of age. She had an axillary adenopathy and a scirrhous carcinoma of the breast, the glands being involved up to the subclavian. Following operation she was kept under observation. Over six months ago last October it was noticed that she had a husky voice. *X*-ray plates were taken and showed a deposit in the mediastinum. Here was a case showing a recurrence after ten years. It was evidently in the mediastinum.

Dr. WILLY MEYER stated that last fall, at the time of the American Congress of Surgeons, he gave a clinic on the final results of carcinoma. He had tried to collect the final data on patients operated on over a period of years. With the shifting population of New York this was impossible to do in the case of ward patients, so one had to take mostly private patients. This effort showed the need of follow-up work. He felt that it was a moral duty to interest the people and show them the value of this work, so that they would give money for social service work. Dr. Meyer said he had brought a few slides. He referred to the two operations that had been before them for many years; the one, he said, might be called the Baltimore, and the other the New York method. The Baltimore method of operating started from the chest toward the axilla and left the clavicular portion of the pectoralis major. This operation involved quite a loss of blood. The New York method started from the axilla. The pectoralis major was divided and had to be removed and the entire mass was removed with the axillary glands without entering the seat of the carcinoma. This operation was divided into two parts, first the removal of the breast with the axillary glands and then the removal of the pectoralis major. He thought that a mistake and that it was better to do it in one operation. He thought the final result of the Baltimore operation was very good, but it must stand to reason that there were often cancerous glands between the pectoralis major and minor and hence it must be better not to enter the site of the disease.

The more experience he had, Dr. Meyer said, the more he was convinced that if any form of cancer should be submitted to radical operation it was Paget's disease, which was the most malignant of all cancers of which we had any knowledge. Radical excision had pretty generally superseded the old Halsted operation.

Dr. LEE, in closing, said that as to the recurrence sixteen years later, it was on the same side and it was thought from its site that it was a recurrence. Dr. Erdmann's case of recurrence at the end of ten years was interesting as showing the type of recurrence one frequently got. Of course, the lymphatics went from the breast into the pleural cavity, and involvement of the pleura occurred more often than of the lung itself. As to what Dr. Meyer had said, they were really using his operation, which was a modification of the Halsted operation. Two of his cases, Dr. Lee said, had axillary nodes, and he did not want to give the impression that he did not operate if the axillary nodes were involved, but when the axillary nodes were involved the chances of recurrence were greater than if they were not affected. Handley thought there was a growth along the lymphatics in an ever-widening circle, and believed he could demonstrate the growth further and further down, even low into the epigastric angle. The preservation of the arm function was well illustrated in the photographs, and showed the nice result that one could obtain by proceeding in the right sort of way. Dr. Lee said he could not agree with what had been said as to the placing of grafts. He believed that in a large number of cases there would be less recurrence

if a certain portion of the skin was sacrificed. Dr. Lee said he had had several cases of Paget's disease. One patient with a large, bulky tumor of the breast, was treated elsewhere for something else. These tumors were rapidly growing, and should be widely extirpated. Dr. Meyer's results in these cases that had survived so many years after operations for carcinoma were very excellent indeed.

Dr. MARTIN L. JAMES exhibited an apparatus, consisting of two glass barrels connected by an automatic valve arrangement, for blood transfusion. It was so constructed that it prevented backflow into either donor or recipient, and as one barrel emptied the other filled. By means of this instrument, Dr. James said, he had been able to transfuse 300 c.c. of blood in less than four minutes. The machine could also be used for venesection, for aspirating, or for giving salvarsan in dispensaries where large quantities had to be injected.

Dr. GEORGE I. MILLER exhibited a small instrument for blood transfusion which he said could be carried in one's pocket and was always ready in an emergency. This device was very simple in construction, could be attached to a 20 c.c. record syringe, and was moderate in price. Dr. Miller had previously presented this apparatus before the Brooklyn Surgical Society.

Early History of Blood Transfusion.—An article by Andruzzi in the *Annali di Medicina Navale e Coloniale* for March-April, 1920, xxvi, i, 3-4, begins with a summary of this practice from the earliest ages. We find vague allusions to it in the writings of Herophilus, Pliny, Celsus and Ovid. There is then a break until 1492, in which year the operation was performed on Pope Innocent VIII. In 1628 Cole of Padua described a method of transfusion, and in 1651 a monk of Metz is known to have devised a crude apparatus with which he made animal experiments. In 1667 a team comprising Denys, a scientist, and Emmerts, a surgeon, after successful animal experiments performed transfusion on human subjects. The place was Paris, the blood donor a lamb. The report of these cases gave a sudden impetus to transfusion, but fatalities were imputed to the method, and in 1675 the French Parliament forbade the practice. After more than a century of latency transfusion cropped out once more in England and Germany. Among the men who became interested in it were Erasmus Darwin in England and Dieffenbach and Hufeland in Germany. During another century the subject was a live one, and it became evident at last that animal blood was unsuited for human transfusion. The period during which this problem of heterologous blood was agitated began in 1812 with the experiments of Prevost and Dumas and continued until 1873 with the experiments of Landois. Modern transfusion has little in common with the original forms. The author fixes the beginning of the modern epoch at 1909, with Crile as its founder. For thirty years before this date transfusion was sidetracked in favor of saline infusion.

Anthrax in French West Africa.—Senegal appears to be well visited by the various plagues, for of late years there have been severe visitations of bubonic plague, while yellow fever occasionally crops out, and the country suffered in common with the rest of the world from the pandemic of influenza. It also appears that for more than ten years past cases of anthrax in cat[illegible] and man have been reported. Teppaz reported cases as early as 1908 and a number of foci have been isolated in which the affection is endemic. The disease begins at the close of the rainy season and augments during the dry season. It occurs by preference in valleys in which the Glossinæ or tsetse flies are active and the trypanosomes of which they are the hosts are at times found in the blood of animals. The latter, however, seem to be fairly immune to the trypanosomes, and it is believed that certain alleged cases of trypanosomiasis in cattle were in reality anthrax. The presence of the latter disease is a severe menace to the native men who eat the flesh and handle the hides of the infected animals. The natives also at times eat the flesh of animals dead of the disease, and have even been known to devour exhumed animals. In some centers there is an inspection of abattoirs and of meat offered for sale, but of an intelligent and efficacious handling of the hygienic problem in such a community there is at present no possibility;

hence every effort should be concentrated on the annual immunisation of the herds against anthrax. There should also be installed a veterinary laboratory in the metropolis of Dakar.—*Office International d'Hygiene Publique.*

Further Data Concerning the Epidemic of Plague at Avignon in 1721.—The first series of extracts from an old manuscript on this subject apeared recently in the editorial columns of the MEDICAL RECORD. The *Progrès Médical* for May 1, 1920, xlviii, 18, publishes another series. These extracts are of much interest in illustrating that sanitary efficiency was greatly in evidence two centuries ago, for many of us are still inclined to the belief that at that period there were available only flight, prayer, incantations, propitiation of offended deities, etc. The medical body was promptly organized and general instructions to the public given out. The latter were instructed not to take the breath of the victims—good advice in the case of pestous pneumonia, which was doubtless the malady in question. Excesses were warned against. Bonfires were good, for they facilitated the destruction of suspicious and condemned objects and enabled the public to see at night. All articles such as stretchers used for transport of victims were at once burned. The practitioners did not all work in harmony with the health authorities, for they concealed cases for bribes, and in fact there was good money in fraud of various kinds. A patient reported plague stricken went to quarantine. One practitioner was doing a good business treating unreported cases secretly at night, but succumbed to his greed, for he contracted the disease. Only the head of a quarantined family was allowed to leave the house to buy provisions. There was a corps of disinfectors active who were evidently allowed some discretion for only certain kinds of articles were burned outright, while others were merely scalded or washed or exposed to the air. Valuable and useful metals were scalded in hot water. An error was committed in looking upon perfumes as disinfectants, these being confounded with deodorizers. There was much use of immunes, which included both survivors from the disease and those with natural immunity. The clergy showed great sense in using everyday experience. Confessions were heard through paper placed over the wickets and priests were placed in the head of the squadrons of "scalders" in the hope of getting better discipline. The immunes were specially employed in connection with contraband, which was often concealed, especially if valuable. We can only regret that more space cannot be devoted to this manuscript, which is a veritable medical classic.

"Practics" and "Practics."—The Washington State Board of Chiropractic Examiners, according to *Northwest Medicine*, recently wanted to curb the board of drugless examiners from licensing another variety of healers who call themselves sanipractic and who, under this designation, encroach on the exclusive privileges of the chiropractic. The judge pronounced a weighty decision, the substance of which was in effect "it can't be done." The lucidity of the Einstein theory of relativity suggests itself, according to the editor, when the different drugless healers clash.

Therapeutic Hints.

Migraine.—Bernard Fantus advocates the following for migraine:

℞ Sodium salicylate..... 6.0
Potassium bromide 12.0
Sodium bicarbonate 12.0
Mix and divide into six blue powder papers.
Tartaric acid 10.8
Divide into six white papers.

Label: Mix contents of a white and a blue paper in half a glass of water. Repeat dose hourly if required.

For very nervous and presumably sensitive persons and for poorly nourished individuals, it is prudent to advise that half the dose be taken at first to see whether or not it might be sufficient. In this manner, possibly disagreeable effects, due to idiosyncrasies, would be avoided.—*Journal of the American Medical Association.*

Epilepsy.—Julius Grinker says that phenylethylbarbituric acid in small doses, from 1½ to 2 grains, once or twice daily, has been found capable of causing an arrest of convulsions in epilepsy. Larger doses than those mentioned are seldom required, but may be safely given. Large doses may be administered when beginning treatment, especially after sudden withdrawal of the bromide treatment; even in such cases the dose may be gradually reduced to what constitutes an average dose, namely, 1½ to 2 grains. No harmful effects have thus far been observed from the long-continued administration of the drug which does not appear to be a habit-forming drug. Patients receiving average doses of phenylethylbarbituric acid do not show the peculiar mental torpor of those taking bromides.—*Journal of the American Medical Association.*

Burns.—McGeary gives the following formula for a simple preparation of paraffin to be used in the treatment of burns:

1. Resorcinol 10
2. Olei eucalypti 20
3. Olei olivæ 50
4. Petrolati 250
5. Paraffin 670

Melt 4 and 5 together. Dissolve 1 in alcohol and add 4 and 5 while the latter is hot, to drive off the alcohol. When cool add 2 and 3.—*Minnesota Medicine.*

Chronic Duodenal Dilatation.—Crouse, discussing the medicinal treatment of chronic duodenal dilatation, recommends the following, or a variation thereof, to be given before food is taken:

Tinc. belladonna .....♏ iii
Tinc. nux. vom.....♏ v
Tinc. cardamon .....♏ xx
Aqua dest. q. s., ad.....℥ i

After food the following may be taken:

Calc. magnesia .....gtl. iv
Sodium bicarb. .....℥ iiss
Eleosach. menth pip. q.s., ad ℥ iv.
Teaspoonful in a half glass of water.

The first prescription is given to check the excessive secretions and to relieve spasm; the latter is given to neutralize excessive acidity.—*Texas State Journal of Medicine.*

ARTERIOSCLEROSIS:

THE THREE-FOLD MENACE OF THE PRESENT DAY.*

BY CHARLES EDWARD NAMMACK, M.D., LL.D.,

NEW YORK.

MEDICAL DIRECTOR, FOURTH DIVISION, BELLEVUE HOSPITAL; VISITING PHYSICIAN, ST. VINCENT'S HOSPITAL; PROFESSOR OF CLINICAL MEDICINE, CORNELL UNIVERSITY MEDICAL COLLEGE, NEW YORK CITY.

So much confusion exists in the minds of medical students, hospital internes, and the profession generally, about the clinical differences between arteriosclerosis and atheroma, that an attempt will be made in this discussion to clarify the situation. This is particularly important at the present time, when the stress and strain of urban life has been intensified during the past three years by the demands made upon our people by the incubus of the great World War, and the subsequent social, financial and industrial unrest caused by that cataclysm. Life in this city has always been strenuous enough, but recent events, with their train of disaster and death in many families, with the increased cost of living, and with the mounting difficulties of procuring labor for the development of our food and industrial resources, have made demands upon the nervous systems of our people greater than the demands of any other period in our history.

It is a military axiom that success in war is not a question of men and money, but of bread and meat. An army marches upon its stomach, and its commissary department must functionate with 100 per cent. efficiency. The history of our Spanish-American War, of the British-Boer conflict, of the Russo-Japanese affair, thoroughly demonstrated this, and emphasized to our Government its prime necessity, when four millions of men and women were transported over three thousand miles of water, amid submerged perils. By the genius and business ability of distinguished civilian and military men, these men and women were kept surrounded not only with necessities, but with comforts. In the human body there are many times four millions of living cells, actively and constantly engaged in warfare against the natural march of decay, and against the unnatural and insidious invasion of disease germs. How shall we maintain our commissary department at the highest notch? It is purely a question of air and food supply. Technically it is called the physiological processes of nutrition. In health, a perfect commissary department is supplied by the heart and blood-vessels. They constitute its purveyors. They not only distribute the food where needed, but with an intelligence conferred by the Infinite Giver of all wisdom, they deliver to each individual ultimate cell of the many billions, the exact kind of selective material needed for its renewal, and, at the same time, remove its waste for excretion by the proper channels. This elementary sketch of the physiology of nutrition may be tiresome to this professional audience, but is well to bear in mind. Do we always try to conserve this wonderful mechanism? Do we stop in our mad rush for preferment, fame, and wealth to consider the vast amount of work done without our conscious intervention by the heart and blood-vessels under the guidance of the involuntary nervous system? The normal heart beating at 72 times per minute, ejects an amount of blood at each systole which requires a force estimated at two foot pounds, to move along the column of blood ahead of it; 144 foot pounds per minute makes an aggregate of over 100 tons of work in each 24 hours, and this is only the minimum, with the body at rest. To sustain this strain we must have a system of vessels which are not merely inert tubes for the conduction of blood, but living vital tissues, a living part of a living whole. It is not remarkable that cardiovascular degeneration occurs so often. It is only remarkable that it does not occur oftener, before man has reached the Biblical three score and ten. Cardiovascular degeneration is especially the harvester of death for medical men, from its three-fold results of nephritis, apoplexy, and heart disease. Statistics compiled some years ago showed that the death rate among medical men from these causes was exceeded only by that of saloonkeepers, butchers, quarrymen, and factory operatives. I therefore offer no apology for bringing this subject to your attention, but only the hope that it may help you to keep your own days long in the land.

I will not inflict upon you any detailed description of the anatomy of the heart or arteries. Studies by recent instruments, supposed to be more precise in their yield of information than were the educated fingers of our revered predecessors at the Bellevue bedsides, have taught us much as to the physiology and pathology of the heart in action, and have helped us to realize the truth of the old axiom, that a man is as old as his arteries. These studies may help, some day, to point the way for man to keep his arteries as young as he would like them to be, and may help our patients to rid themselves of that bugbear which is called arteriosclerosis. This terrifying term lacks the satisfying unction of "that blessed word Mesopotamia," in the Highland lady's system of theology, but is just as mysterious to the laity. What is arteriosclerosis? Is it a "disease,"

*Read before the Society of Bellevue Hospital Alumni, October 6, 1920.

or an effect of diseases, many and various? How does it differ from atheroma?

Definition.—Arteriosclerosis is a hyaline degeneration of the structural elements of the arterial wall, with connective tissue substitution, hyperplasia, and subsequent contraction with induration, whereby the characteristic functions of the vessel wall—retention, absorption, metabolism, with the power of extension and contraction, are weakened or lost.[3] It is a pathological condition, and may arise at any age, in early life, in childhood, or even in infancy. Atheroma, on the other hand, is the usual accompaniment of advancing age, and is a physiological condition. At the post-mortem table both conditions may be found in the same subject, hence the confusion that occurs in our minds. Even Osler, usually an apostle of clarity in teaching, includes arteriosclerosis and atheroma in one definition.[4]

Pathology.—In the aorta and its large branches there is much elastic tissue and relatively little muscle. As the arteries approach the organs to which they are distributed, this proportion changes, so that the supply of blood may be increased or decreased as needed. Hence it is in the arterioles or smaller arteries that the lesions of arteriosclerosis do the most damage. Pathologically we find four types of lesions: (1) nodular; (2) diffuse; (3) senile; (4) syphilitic. In advanced arteriosclerosis all types or grades may be found. The nodular form is found particularly on the aorta and large vessels, especially at or near the orifices of branching vessels.

In the diffuse form the whole arterial system is rarely, if ever, attacked uniformly. We may have pipe-stem radials with a smooth aortic lining, but with enlargement of the aorta and thinning of its coats and loss of elasticity. The senile type leads eventually to calcareous deposits in the intima, with widened, elongated, inelastic aorta.

In syphilitic aortitis, plaques form which, instead of undergoing an atheromatous change, as in the nodular form, are prone to scar formation with puckering. *Spirochetæ pallidæ* have been found in the degenerated media, and in small gummata beneath the intima. The Wassermann reaction should be tested in every case of aortic insufficiency, and the pulse pressure reading carefully recorded. In the smaller arteries and arterioles three kind of changes occur: A muscular hypertrophy; a fibrosis of all the coats; or a marked proliferation of the intimal endothelium, leading in time to endarteritis obliterans. Other poisons than syphilis can produce the same set of changes, the essential lesion in the large arteries being a degeneration of the middle coat, followed by an hypertrophy of the intima, layer upon layer being added in an attempt to restore the strength of the vessel. The results of experiments, upon rabbits and dogs, to produce arteriosclerosis by injection of adrenalin, barium chloride, digitalin, physostigmine, nicotine, and other drugs, as well as by feeding animal proteins to rabbits, have been very discordant, and have not added much to our knowledge of the subject. The toxins of the typhoid bacillus and the *Streptococcus pyogenes* have produced changes somewhat analogous to the intimal proliferations found in the human aorta, thus confirming the clinical observations of Thayer and others that individuals who have had typhoid fever have more palpable arteries than other individuals of equal age.

Etiology.—There are various causes for arteriosclerosis, such as heredity, age, sex, alcohol, venereal disease, rheumatic fever, other acute infections, high living and hard work. While the devotion of doctors is primarily given at the shrine of Minerva, and not at those of Venus and Bacchus—although the latter is now only a source of wistful archæological study, the doctor must make also the anvil of Vulcan ring, not literally with hammer and spark, but with the constant impact, upon the billions of the functional nerve-cells of his brain, of the woes and worries of his patients, of the increasing demands of his landlord, and of the tire-troubles of his vehicle. The influences of heredity we cannot forestall, since we are not allowed to be judicious in the selection of our ancestors, but we can minimize the damage by avoiding their mistakes. Age is something that nightly pitches our moving tent a day's march nearer home, but if we travel with a contented mind, and a little faith that the road, whether we believe that it leads over Mt. Sinai or over Mt. Calvary, finally stops at the Father's house, we can laugh at the old gentleman with the exuberant whiskers and the rusty scythe who marched by our side. The influence of sex disparity in producing strain will probably lessen as the world goes on, now that our beloved sisters stand side by side with us in the marts of trade, in the ranks of professions, on the battle field, and in the direct primaries. Alcohol is likewise a fading specter, since a clamorous minority have dictated to the medical profession how they shall not treat pneumonia, septicemia, and other acute infections, but leaves to the old soak his accustomed sources of underground supply, without the necessity of a prescription with a ten-day limit for each pint; still, for the well-to-do, who find the call of the wild too urgent, George Bernard Shaw points out that there is a free country only seven days away. Syphilis is the predominating factor in arterial degeneration in the young, and may attack any of the three walls of the vessels, affecting the brain by preference because syphilitic arteritis is localized in arteries supplied with lymphatic sheaths. The conditions that keep up high blood tension, such as the endogenous poisons of perverted metabolism in gout, diabetes, chronic nephritis, and obesity, all lead to arterial thickening and subsequent degeneration.

Overeating, that is to say, food in excess of work and excretion, is another potent cause, causing the hyperemia, or hyperpiesia, so well described by Sir Clifford Allbutt.[5] Allbutt was one of the first to point out that not all cases of arteriosclerosis are attended by high blood pressure. He makes three classes, viz.: (1) high pressure arteriosclerosis; (2) involutionary or decrescent (senile); (3) infectious or toxic. Allbutt believes that there are two modes of hereditary transmission, the direct and the indirect; the direct consisting of an original frailty or toxic susceptibility which may run in families; and the indirect, which apparently depends upon a proclivity to some ill-understood poisoning or perversion. He insists that arteriosclerosis is not a disease, in the sense in which we speak of tuberculosis or pneumonia as a disease, but in reality is an

effect of many and various diseases. Warfield emphasizes the same point, but considers that syphilitic arteritis may be viewed as an entity, because the cause is known and the lesions are characteristic. Mental strain, except in those care-free persons who laugh their way through life, is a frequent cause. It is not the work, but the worry, that results in high tension, arterial strain, compensatory thickening, and hypertrophied heart. Muscular over-work, especially when combined with alcohol and coarse heavy food, is frequently seen as an operating cause among the laboring class, both whites and negroes, but especially among the latter. Renal disease, especially the contracted red kidney, or the clinically shrunken and scarred kidney, the so-called arteriosclerotic kidney, may be either causative or resultant. He who predicts, however, from the results of uranalysis, what type of kidney will be shown at autopsy, is rushing in where angels might fear to tread. Functional response of the kidney, as shown by appropriate tests, is a better guide than pathological classification. Endocrinology is at present fascinating its followers as being the responsible agent in this, and in almost all diseases. The current literature abounds in speculative and imaginative theories and explanations, but this hay is often a little high for the short horses.

Symptomatology.—The story of arteriosclerosis must go back a long way, perhaps even into the third or fourth generation. So much of it depends upon the quality of arterial tissue inherited that a careful family history is desirable. Next the personal habits and history of previous diseases must be elicited. It is doubtful that sclerosis itself would produce recognizable symptoms or physical signs, did not the diseased arteries fail to carry a sufficient supply of blood to the various organs and in that way cause derangements of function. Hence the clinical picture varies, according to the organ primarily or chiefly affected. Thus we may have symptoms referable to the general system, or local manifestations pointing to nervous, cardiac, renal, abdominal, or peripheral arterial mechanisms. Manifestly a condition of so protean a nature cannot be briefly described. The symptomatology sometimes makes the diagnosis easy and certain, sometimes only presumptive, sometimes impossible. Well developed arteriosclerosis shows four pathognomonic signs: hypertrophy of the heart; accentuation of the second aortic sound; palpable thickening of the arteries; heightened blood pressure. All need not necessarily be present to establish the diagnosis. Prior to the development of these changes, minor alterations in the various functions of the body must be patiently sought for, in the light of the well known etiological factors. Periodical examinations, of subjects who believe themselves to be entirely well, are of great benefit in uncovering those minor manifestations of disease which taken at the flood lead back to health, but neglected, voyage ahead to irreparable damage. A detailed recital of all such changes would transcend the limits of your patience. The value of careful blood pressure studies, especially studies of the pulse pressure, cannot be too often insisted upon, but blood pressure readings, like Opie's colors, must be mixed with brains to be useful guides. Hypertension itself is practically always a compensatory process, and should be regarded as one regards a compensated heart lesion. It may be not only essential, but actually life saving, but, when it tends to increase, we must try to reduce it.

Diagnosis.—A good history is half the diagnosis; in some instances the whole diagnosis. Supplementing this by careful bidigital palpation of the arteries, by correct interpretation of the blood pressure readings, by accurate estimation of the heart's size and power, and by direct ophthalmoscopic inspection of the retinal vessels, a diagnosis can usually be established. The ophthalmoscope especially is useful in early diagnosis and shows changes which may not only be suggestive but even pathognomonic. In the young, hereditary influences play an important role, a history of syphilis insufficiently treated, or of the abuse of alcohol, in the family history being particularly significant, as is also a history of gout and rheumatism. Among the infectious disease, the story of a long siege of typhoid fever bears great weight. Severe prolonged laborious occupation, or mental strain, should be carefully considered. I do not believe that the use of tobacco in moderation is especially deleterious, even though it has been experimentally demonstrated that the smoking of one cigar after dinner entails a loss of 20 per cent of the energy provided by a good dinner.

Differential Diagnosis.—This requires the exclusion of pseudo-angina pectoris, true angina pectoris, peptic ulcer, appendicitis, or other inflammatory abdominal conditions. Warfield gives the following differential tables:

PSEUDO-ANGINA PECTORIS	TRUE ANGINA PECTORIS
Etiology rather uncertain; hysteria, neurasthenia, toxic agents, and reflex conditions.	Etiology not certain, but almost always associated with arteriosclerosis of the coronary arteries, and also aortic regurgitation.
No age is exempt; usually in young people, especially females.	Age is important. Rare before forty, and males usually affected.
Paroxysms of pain occur spontaneously, are periodic, and often nocturnal.	Paroxysms brought on by overexertion or excessive mental emotion. Rarely periodic.
Pain, while severe, is diffuse and sensation is of distention of the heart. No sense of real anguish.	Intense pain, radiating down the arm; heart felt as in a vise. Sense of anguish and impending dissolution.
Duration may be an hour or more. Restlessness and emotional symptoms of causative conditions are prominent. Usually no increase in arterial tension. Prognosis favorable.	Duration from few seconds to several minutes. Silent and fixed attitude, rigidity rather than restlessness. Arterial tension as a rule increased. Prognosis most unfavorable.
PEPTIC ULCER.	ANGINA ABDOMINALIS.
Occurs as a rule in young persons, most often females.	Occurs only in adults over forty who have been heavy eaters and drinkers, mostly males.
Pain of boring character, increased by food and by certain positions with reference to stomach. Felt through to left of spine. Occult blood found in stools. Considerable anemia apt to be present. Arterial tension usually low.	Pain, cramp-like, diffuse, but more localized in epigastrium. Not necessarily connected with food. No occult blood in stools. Anemia often absent. Arterial tension high (splanchnic sclerosis).

Prognosis.—In a disease so variable in its manifestations, an accurate prognosis is no easy matter. The chief factors to be considered are: (1) the site of the sclerosis; (2) the probable stage; (3) the existing complications, and (4), last and most important, the patient himself, his habits, his character, and his mode of life. In any event, the prognosis should be most guarded. In the cardiac form, angina pectoris, apoplexy from cerebral hemorrhage or embolism or thrombosis, may supervene without warning. In the arteriosclerotic kidney, uremia may develop from slight indiscretions or without assignable cause. When the disease is localized in the peripheral arteries, gangrene may result, or the minor but uncomfortable seizures of Raynaud's disease or erythromelalgia. The cerebral type with its early dizziness, dullness, inability for mental concentration, and mental irritability should put us on our guard. Intestinal hemorrhage is a grave sign, as an indication of splanchnic sclerosis, possibly leading to embolus or thrombus of the superior mesenteric artery, or in smaller branches to necrosis and ulceration of the intestine.

Prophylaxis.—Decay and degeneration of tissues are necessary accompaniments to the song of life, and none of us can escape growing old. We cannot prevent the heart from beating out its 100 tons of work a day, nor relieve the arteries of their strain. Yet with the inheritance of a healthy organism and proper care of his machinery, comparative anatomy and physiology would allow man a duration of life equal to that of the one-hoss shay. Herbert Spencer's definition of life is that it is "the continuous adjustment of internal relations to external relations." This means that we must get the maximum amount of work done with the minimum amount of wear and tear on the vessels. In these strenuous times, this is difficult, but not impossible. It is not the work, but the worry, that leads to arterial degeneration. Work, with a contented mind, moderate appetites, and modest ambition, will strengthen and develop rather than weaken the bodily forces. Excesses of any kind, be they mental, moral, or physical, tend to wear out the organism. Judicious exercise and well chosen diet are the principal things to discipline ourselves about. Successful doctors complain that they have no time for physical exercise, such as walking, but prefer the lolling luxury of a limousine while making calls. Alonzo Clark who walked and worked until his eighty-fourth year, remarked that when a doctor needed a horse to pull him around he must be weak in the legs, and if he needed two horses, he must be weak also in the head. The city doctor's horse has disappeared, to give place to the rapidly moving automobile, and to encourage obesity and lead to Sir Clifford Allbutt's hyperpiesia. Such are the sweets of prosperity. Every man and woman over forty years of age should have the equivalent of four miles walking in the open air every day. Given sound heart and lungs, this will occupy about one hour. If they have the opportunity to visit the neighboring golf links, and do this walking over an eighteen-hole course of springy turf, with the additional training of the eye and hand and of the control of temper which comes with the mastery of the elusive pill, so much the better. The nineteenth hole now lives only in mournful retrospection. Scholastic philosophy teaches that the chief end of man is happiness; not merely pleasure, for pleasure only depends upon the possession of things, and things decay; not joy, for joy depends upon the possession of friends, and friends die; but spirituality, which depends upon the possession of character, and character is immortal. Old age does not invariably lead to hardening of arteries. A patient of mine, who wrote at least one book every year until her eighty-fifth year, and the spirituality of whose writings has been a comfort and solace to millions of readers, had the soft arteries of a woman of thirty, and a blood pressure of 120.

Treatment.—It is manifest from what has been said that there is no routine plan of treatment for an essentially chronic progressive disease like arteriosclerosis. The keynote is individualization, study of the patient with the disease. This cannot be learned from reading text-books or journal articles, nor even taught at bedside clinics. Teachers can only teach what they are, not what they know. Our old friends, general principles, can be given in the way of advice, by way of prophylaxis, provided we catch the patient early enough in life. After that, it will depend upon our personal influence over the patient, and his own stability of character, whether we can correct the injurious influence of his environment. Every man is more or less the arbiter of his own fate. The one essential in the diet for a patient is reduction in the amount. Americans eat too much, as a rule, but those who have traveled in German and Scandinavian countries will admit that by comparison we are abstemious, if not penurious, eaters. Meat has been so abundant in this country that few meals are considered complete without an abundance of meat and sweets. Herbert Hoover deserves the everlasting thanks of this generation, even though he be denied their votes. A diet of vegetables, fruit, fish, bread and butter, and milk, with very little meat, will suffice in most cases. The supposed injurious effects of the lime salts in milk can be avoided by the addition of lime water, which precipitates the soluble lime salts in the stomach, and facilitates their excretion by the intestines rather than by the kidneys. Buttermilk, either from the churn or from the *Bacillus acidus lacticus*, may furnish an agreeable substitute for sweet milk. Balneotherapy demands careful individualization also. Our generation is certainly a bathing one, but it is folly to encourage the morning cold bath to those who do not react glowingly after it, and criminal to advise the Turkish or Russian bath to one with degenerated cranial arteries.

The one drug to which we turn, for the prescription which most patients expect in return for the fee, is iodide of potassium. Its action has been the result of much controversy. Some writers believes that it acts as a vasodilator and thus decreases blood pressure. Others that it lessens the viscosity of the blood. Capps[9] denies that it does either and says that its only benefit is selective absorption of the cellular exudate in syphilitic arteritis. Lemoine[10] believes that iodide of potassium is a therapeutic heresy. C. T. Hood[11] states that it is now generally conceded that iodides and iodine have no place in the treatment of hypertension or arterial

fibrosis. His own hypothesis is that salt-poor and salt-free diet should be pushed to the point of removal of the surplus sodium chloride from the body, and to keeping the tissue sodium chloride content at the physiological amount. To help to accomplish this he advocates administering one per cent solution of potassium nitrate of which fifteen drops are to be taken three times a day in half a glass of water until the individual is filtered of his excess chlorides.

Long before the endocrinists held their present sway, it was believed that the thyroid secretion and that of the adrenals were antagonistic, and small doses of thyroid extract, half a grain twice a day, were given with benefit to reduce hypertension. But it is not always wise to reduce hypertension. It is perhaps fortunate that our well meant efforts to accomplish reduction do not always succeed. Nitroglycerin will usually fail, as it is eliminated in about thirty minutes. Sodium nitrate will hold a slight effect for about two hours. There is no question about the efficacy of amyl nitrite in anginal attacks, and many elderly patients of mine are profuse in their verbal expressions of gratitude for its presence at their bedsides at night, or in convenient vest-pocket pearls by day. Benzyl benzoate has recently been lauded by Macht in angina, and in other spasmodic seizures. I would put tincture of aconite into the hands of a careful nurse, or hospital interne, for use in excessive hypertension, but would want the effects carefully watched, and the results checked by the sphygmomanometer. But the greatest good is done for our patients in Bellevue and St. Vincent's by absolute rest in bed. Karell diet for four days, hot packs, and free purgation, with venesection added in uremic convulsions or coma. Morphine is sometimes invaluable to secure rest at night, but it should never be forgotten that morphine checks all the secretions but one, and that the habitual use of morphine is the beginning of the end. Influenced by the teachings of the late George L. Peabody in the New York Hospital, I have made extensive trial of amylene hydrate in hot milk at bedtime. Some patients swear by it, many others swear at it. It can be given by rectum when the stomach is intolerant. The Trunecek serum has gone the way of all fads. The treatment of the later stages of arteriosclerosis becomes that of the damage done in brain, heart, kidneys, or intestines, and opens up too wide a field to be covered in this discussion. Prevention, by recognizing the disease in its early stages, must after all be our watchward. Of the 73,266 deaths in the city of New York in 1912, 7251 occurred from organic diseases of the heart; 7104 from nephritis, and from cerebral hemorrhage and softening 2805.[9] In the total registration area of the United States, approximately 23.2 per cent occurred from these causes. The percentage in the rural districts alone was 26.7, thus showing that the urban mortality is less than that of the rural. This is contrary to the usually accepted opinions of the back-to-the-soil prophets.

New York State has a slightly better showing, the tables of the combined cities of the Empire State giving a rate of 20.5 per cent of the total mortality, while the rural portions furnished figures of 22.3 per cent.[9] New York physicians may therefore lay this flattering unction to their souls, even though the City of New York does not measure up to its vaunted standard of excellence in hygiene and sanitation. Other tables will show that this disproportionate loss of life occurs during the ages of from thirty to sixty years, the period of greatest productivity. It is improbable that therapeutics will work wonders in decreasing this mortality for many years to come. Still we must labor to increase our efforts at "preventability." Preventability is defined by Irving Fisher, in the report of the National Conservation Commission on National Vitality, as follows: "A ratio of preventability is the fraction of all deaths which would be avoided if knowledge now existing among well informed men in the medical profession were actually applied in a reasonable way and to a reasonable extent." The practical meaning of this is that we should instruct our patients in the underlying etiological factors of this group of diseases. Such a scheme of instruction would include the elaboration of plans for the elimination or control of contagious and infectious diseases, for the elimination or control of conditions causing poisonings and intoxications, for the supervision and regulation of conditions inducing abnormal physical strains, and for minimizing the mental stress of the community.[9]

Along this road, social service and social hygiene are making steady headway, but the way is long and rough, and we who are traveling it can only lend a hand to those others who are weary and heavily laden, to make smooth the path for them. I commend to your earnest attention the comprehensive plan outlined by Ira S. Wile in the MEDICAL RECORD for June 5, 1915, which well deserves our careful study and active cooperation. If "health is purchasable" as alleged by our Health Departments, its cost, in these days of luxurious extravagance, should not be a deterrent. Dr. Wile's scheme may sound Utopian, and difficult of accomplishment at the present time, but if we all bend our backs to the task, it may come about in the present generation.

"We are all weary travelers along Life's dusty way,
If any man can play the pipes, in God's name let him play."

THE USE OF FRESH VACCINES IN WHOOPING COUGH.

By ROWLAND G. FREEMAN, M.D.,

NEW YORK.

VACCINES for the prevention or cure of whooping-cough have been used for the past eight years, and while some enthusiasm has been shown by certain writers, the general opinion has been that they were of but little service in the treatment of whooping-cough, although possibly of some value in its prevention. My own attitude was that they did not modify the course of whooping-cough, and I had never seen a case of whooping-cough apparently prevented by their use.

I administered them occasionally, because the parents thought they might do some good, and I knew they would do no harm, but with no more effect than was apparently obtained from drug treatment.

The diagnosis of whooping-cough I have usually confirmed by a blood count, the high lymphocytosis giving one a characteristic picture of this disease.

Two years ago I saw Dr. Huenekens' paper on the application of the complement fixation test for the detection of antibodies after the injection of whooping-cough vaccines, in which he showed that the antibodies were not present unless the vaccines were freshly prepared, and that after a week of storage but little antibody production resulted from their injection even in large doses.

It seemed to me possible that this fact might explain the contradictory reports from the use of whooping-cough vaccines, as some clinicians had probably used fresh vaccines by accident in the course of their work. I felt that at least this should be tried out, and intended myself to do so in some institution. I regret that I am unable to report any institution work, but I have brought together all the cases in which I have used it in private practice, hoping to stimulate interest in the use of these fresh vaccines and thus render it easier to obtain them, for it requires from one to two weeks to produce fresh vaccines and some cases for which I ordered them have been so far along in the disease by the time they were obtained that one could expect but little effect on the course.

If we are to have opportunity to give the vaccines a fair trial we must have some laboratory producing vaccines every week.

As to the general principle of vaccines being useful in proportion to their freshness I was told by a representative of the Lederle Laboratories in New York that gonoccoccus vaccine loses in two days 30 per cent. of its efficiency, and Dr. Fleischner, in the discussion of Dr. Huenekens' first paper, showed that there was some deterioration in the immunizing properties of the tuberculin vaccine on keeping. Dr. William Hallock Park of New York has told me that there is undoubtedly a slow deterioration in all vaccines on keeping; that this deterioration is more rapid in some vaccines than in others.

Immediately after seeing Dr. Huenekens' article I was called to a family with one child who had been coughing for ten days and having paroxysms for a week with vomiting, and a second child who had only begun to cough and who before the first injection had whooped once. A vaccine two weeks old was injected in both children with no material result, but after the first injection of fresh vaccine the youngest child, who was well advanced in the disease, ceased vomiting and had little cough, while the second child did not cough at all after the injection.

A little later I was called to another family where a baby of eight months had had whooping-cough very severely for some time, and about whom the family were very much concerned. In this family also was an older child who had just begun to cough. The baby was materially better after the injection of the vaccines and the other child stopped coughing.

Another case which was far advanced in the disease showed slight but not material effect from the injections.

Recently I have used these fresh vaccines in a number of cases.

J. M., six years old, with two weeks' duration and severe paroxysms, stopped whooping entirely after three injections.

Another boy, four years old (G. W.), with very severe vomiting and paroxysms, had a cessation of the vomiting and paroxysms after injections, and one boy (W. F.), of nine years, had had paroxysms for a number of days. The vaccine appeared to cure him almost entirely.

A boy of ten years (S. F.) was very materially improved. Another boy of the same age (E. P.) did not have severe paroxysms or severe cough, and did not receive much benefit from the vaccines, the first dose of which was of vaccines three months old, the second, one month old, and the last fresh vaccine, but this child was well advanced in the disease by this time.

Another family (C.) of two children, aged seven years and two years, reported that the paroxysms were less frequent and the vomiting stopped, but the vaccines apparently did not shorten the course of the disease.

Very recently I had occasion to use these vaccines in two families, one of six children in which three of the children had recently begun to whoop; and one of three children in which the baby, two years old, was having paroxysms. Here we seemed to have a good opportunity for treatment and prophylaxis.

In the family of six children the first injection of one-half billion of vaccine which was twenty-five days old, produced no improvement. A second and third injection of fresh Lederle vaccine was also followed by no material change. For the fourth injection I had an absolutely fresh Board of Health vaccine and obtained no material reaction, therefore, no more injections were given and the children were sent to the country. In this family I could not feel that the vaccines had any effect at all. The children who had the disease still had fairly severe paroxysms after the fourth injection, while the three children who were given prophylactic injections developed whooping-cough, although not of a severe type.

In the other family of three children, after the first injection of one-month-old vaccine in the child who was having paroxysms, no more paroxysms were observed, and the other two children have never coughed since.

To summarize then, in sixteen children with whooping-cough in which the vaccines were used at various periods of the disease, in five no results were obtained. Of these five children three were early in the disease and the other two very late.

Of the eleven remaining cases, in nine a very material improvement took place and in four of these a practical cure was obtained.

Of the five cases in which prophylactic doses were used two were successful and three failed.

My confidence in these vaccines has been somewhat shaken by the results in this family of six children who failed to react, but the good results obtained in other cases and the quite remarkable results obtained in certain beginning cases convince me that these fresh vaccines should have an extended use, particularly in institutions where controls may be used to demonstrate whether we may not have in these vaccines a valuable method of reducing the large mortality from whooping-cough.

The dosage used in all the above cases was one-half billion for the first dose, one billion for the second dose, and two billion each for the third and fourth doses.

BOTULISM.

A REPORT OF FIFTEEN CASES, IN THREE SERIES.

BY G. M. RANDALL, M.D.,

NEW YORK.

MAJOR MEDICAL CORPS, U. S. ARMY, RETIRED.

IT is advisable to make public all that we know concerning this malady, in which there has been but little advancement of knowledge in the past half century. Early recognition and early treatment give the only possible hope of recovery in any given case. We have even every reason to believe that there is now no known antitoxin potent enough to save life when the symptoms are once established. Prophylactic use of an antitoxin suggests itself along the same lines as diphtheria and tetanus antitoxin. This would obviously be expedient where sporadic cases had occurred and the source was unknown.

These cases occurred in three series; Four in Lowell, Mass., in 1912. Seven in Tampa, Florida, in 1916, and four in Maine, in 1920. The Lowell cases were as follows:

CASE I.—G. A., male. Age 32. Born in Greece. Employed in a cotton mill. Moderate drinker of light wine and beer. Heavy drinker of coffee. Well nourished. Intelligence poor. Patient had been ill about twenty-four hours when I first saw him. Symptoms: Facial expression and appearance that of extreme dejection and apathy. Slight ptosis of right eyelid. Could protrude the tongue only with difficulty and slightly. Much difficulty in swallowing liquid or solid food. Articulation was indistinct and labored. The throat symptoms so closely resembled peri-tonsillar abscess that I made a "snap diagnosis" in my mind, but on careful examination of the throat I found it perfectly normal in appearance. There was marked increase in the salivary secretion, which was thick and stringy. This he continually wiped away with a rag. Pulse 80. Temperature by mouth 98.2. Respiration 22. No nausea or intestinal symptoms. Great muscular weakness. Pupils equal and responsive to light. Tendon reflexes normal. No pain, but rather restless in bed. Said to have eaten some "blood sausage" about thirty hours before he called the doctor. The sausages were made by Greek laborers, from some pork scraps which they were accustomed to purchase at a slaughter house in an adjoining town (Methuen, Mass.). The sausage "casings" were the large intestine of a hog. The sausages were boiled in water before eaten. They were eaten at about 7 P. M. and the first symptoms developed on arising the following morning.

The treatment was eliminative and stimulating. Calomel one-tenth grain every thirty minutes until one grain was taken then one ounce of castor oil. The cathartic acted well but the symptom in no degree diminished. Strychnine in one-fortieth grain doses was given hypodermatically. Rectal nutrition was undertaken. The patient grew progressively weaker, with the appearance of intense toxemia, resembling the toxemia of diphtheria or tetanus. No temperature developed at any time. Patient died on the fourth day of his illness. Terminal symptoms related to cardiac failure. No autopsy.

CASE II.—J. K., female. Age. 12. Born in Greece. Poorly nourished. Same family as Case I. Seen at same time. Child ate of same sausages as Case I, at same time. Symptoms: Vomiting and abdominal pain (which in my judgment was due to the fact that the child drank some milk at the same time she ate the sausage). Much flatulent distension of the colon. Pulse 102, temperature 101. Difficulty of articulation and swallowing. Drooling of a thick saliva. Extreme prostration. No ocular symptoms.

The treatment was bismuth subnitrate, with beta-naphthol and hexamethylenamine with caffein-sodio-benzoate as a cardiac stimulant. This was used hypodermatically. No results from stimulation. Patient died on the fifth day of her illness, the heart continued to beat after respiration had ceased three or four minutes. This might have been due to the caffeine. No autopsy was permitted.

CASE III.—C. H., female. Age 31. Housewife. Born in Greece. Rather undernourished and of anemic appearance. History of malarial fever in Greece. Same family as the two previous cases. Ate of same sausage at same time. Symptoms developed about noon the following day. Saw patient about ten hours after the first symptoms of illness. Marked muscular weakness so that she staggered when attempting to walk, although she had no vertigo when sitting or lying down. Bilateral blepharoptosis, pupils responded slowly to light, marked diplopia, and nystagmus of the right eye. No nausea or intestinal symptoms.

The treatment was saline cathartics with enemata to which glycerine was added. Thymol was given in three-grain doses every three hours. Cardiac and respiratory stimulants were used hypodermatically, but no response was obtained and the patient died on the third day of her illness. Terminal symptoms were pulmonary hypotasis, with marked œdema but no consolidation. No post-mortem was permitted.

CASE IV.—G. K. Male, age 52. Born in Greece. Laborer. Well developed and nourished. Ate of the same food as the three preceding cases at the same time. Began to feel sick about 4 p. m. of day following eating of the ham (which as previously stated was at 7 p. m.) Symptoms practically the same as the three preceding cases. Muscular weakness was if possible more marked and there was a slight paralysis of the facial muscles on the right side. The urine, which I have the record of, showed renal insufficiency. It was high colored, large trace of albumen, normal solids absolutely diminished. We expected the patient to develop comatose symptoms but respiration failed and the patient died on the fifth day of his illness. Paralysis of the diaphragm was very evident as a terminal condition. The heart continued to beat for a few minutes after respiration ceased.

These cases were seen in consultation with Dr. Andronopoulos of Lowell, Mass. The cases were

early diagnosed as "ptomaine poisoning," but a careful laboratory examination of the sausage demonstrated *Bacillus botulinus*. Growths were made in glucose-gelatin and agar tubes and later plated on glucose-gelatin plates. Colonies were picked and those that were surrounded by a liquid zone of gelatin proved to be the characteristic round-end, spore-bearing, Gram positive, anaerobic *Bacillus botulinus*.

Pure cultures of these organisms were fed to a cat, a dog, and a rabbit, with no pathologic results. The same colonies were further incubated and cultured and filtrates made from them and the filtrates given by mouth and intra-venously, to the same animals. Symptoms developed first in the rabbit, then the dog and last the cat. Symptoms in the animals were; muscular weakness, slowing of the rate of respiration. The dog lived twenty-six hours, from ingestion of culture. The cat staggered around a few hours longer. The conclusions that we came to were that the first cultures that we fed to the animals had not had time to develop toxines of the potency of the later grown organisms. (?) There were some facts well established by our experiments; the toxin of *Bacillus botulinus* is filterable. Its lethal properties are not impaired by a temperature of 212° F. maintained for ten minutes. The exact amount of toxin given in any one of the animal experiments was not known. The only way this could be done would be by standardizing it in the same way as that in use in standardizing other toxins and antitoxins, and our laboratory was not sufficiently well equipped for this.

The next series of cases of Botulism that I saw were in Tampa, Florida, while I was Post Surgeon at Fort Dade, Florida, in 1916. I was called in consultation with the Port Surgeon who was also Quarantine Officer Acting in absence of the Port Quarantine Officer who was thirty miles down the Bay.

Seven sponge fishermen were ill in their little "sponge boat." One man was dead, five were quite ill and one was but slightly ill, mostly from fright. This last man had been seasick the day before and had eaten nothing for two days. (There are compensations even in seasickness.) The scene presented was, to use a brief and good southern expression, "*s-o-m-e* mess." Filth of all kinds known to sailors was there. Odors of bilge-water and gasoline, dead fish and stinking sponges hanging in the shrouds to "cure" and dry, the galley was absolutely unspeakable for its filth. Immediately on arrival in port the cook had gone uptown and purchased a native "razorback" ham, some eggs and other articles of food, which were partaken of by all except the seasick man at about 6.30 p. m. They began to be ill the next morning. It did not require much Sherlock Holmes "deduction" to conclude that it was food that was causing the trouble. It had been at first thought to be some unknown disease brought up from Mexican or Cuban ports.

Our treatment was begun in a rational manner, *i. e.*: elimination and stimulation. I took specimens of all of the food back to the Post Hospital and set about examining it, as I had done in the Lowell cases. I had canned string beans, canned corn, canned milk, macaroni and ham. To make a long story short the only pathogenic organisms that I found were in the ham. One of my first tests was to macerate some of the ham in sterile normal salt solution, and give some of the liquid to a cat. The cat developed symptoms of poisoning in about six hours, staggering gait and lassitude. The cat died in about twenty-four hours. A particle of the ham was scraped from around the lower end of the ham bone and put in a capsule the size of a pea and given to a small yellow dog with a bit of other meat. He developed the usual symptoms. His muscles of deglutition were completely paralysed. He lived thirty hours after taking the capsule.

The media which I used in the culture of the organisms in these cases was lean beef infusion, with 3 per cent. of glucose, 2 per cent. of peptone, and 1 per cent. sodium chloride. This gave very excellent growths of *Bacillus botulinus*. Toxin from these cultures was especially virulent.

The symptoms of the fishermen were all characteristic; diplopia, difficulty of deglutition, and articulation, increased secretion of viscid saliva, blepharoptosis, nystagmus in two cases, great muscular weakness, all neurologic symptoms related to the cranial nerves, viz.; first, third, fourth, fifth, sixth, eighth, ninth and tenth. Paralysis of the diaphragm was conspicuous in three cases shortly before death. They all complained of lack of air and brought all accessory muscles of respiration into play with greatest effort. The mind of each was clear to the very last. There was no elevation of temperature in any case except the little girl, who had a co-existent intestinal disturbance. No case lived beyond five days from eating the ham The first case to die, lived only eighteen hours after eating the ham.

The ham as found did not have any bad appearance or bad odor. Neither did the tube or plate cultures have any peculiar odor. I ought to say in passing that I gave about four ounces of the tube and plate cultures to an Army mule that had been "surveyed" and "condemned," and was officially dead, but actually enjoying the best days of its life browsing and grazing about the fort. It was fed to him (or it) with a little sugar on a wisp of grass. No harm came to the mule. The immunity of the mule is quite worth while to study further.

My next experience with *Bacillus botulinus* was in June and July, 1920, at a Summer resort in Maine. And while any fair-minded bacteriologist would attach no blame to the management or the food supply, the exact spot would better be withheld from broad publicity, though the cases are well known to the State Health Commission, as well as to several consultants, including the County Medical Examiner and Henry Dwight Chapin, M.D. of New York. June 29-30, 1920, there developed four cases of illness all of which resulted fatally. The clinical history of these cases is as follows:

CASE XII.—A. R. Female, age 62. Born in Ireland. Employed as "scrub-woman" in hotel. Well nourished, rather senile in appearance. Had up to two years ago used alcohol rather freely. Called to see her on the second day of her illness. In bed. Symptoms: Diplopia, diminished tendon reflexes, profuse secretion of thick saliva which she wiped from her month as she was unable to swallow without much effort and nearly choked when the effort was made. Articulation was difficult and indistinct. Much nausea and vomiting on taking liquid or solid food. No nausea at any other time. Pulse 78, temperature 97.2. Respiration 22. Bowels constipated but acted after active catharsis. Insomnia and great muscular weakness. Early on the third day patient began to show marked failure of the respiratory function, and paralysis of the diaphragm soon was evident and at 2 p. m. she died of respiratory failure. No autopsy.

CASE XIII.—J. D. Male, age 47. Well nourished, temperate, intelligent, spare of habit. First called to him on the second day of his illness. In bed. Temperature 97.6°, pulse 80, respiratory 24. Symptoms so closely resembled quinsy or peri-tonsillar inflammation that I took temperature a second time by rectum (which I was surprised to find no elevation of temperature, and the only temperature worth taking). Careful examination of the throat failed to show any inflammatory condition. He had much difficulty in articulating and swallowing. There was profuse viscid saliva, which he allowed to run from his mouth on to a cloth. Ptosis of right eyelid, slight paralysis of the facial muscles

on left side. Diplopia, facial expression was blank, which was quite different from his usual habit. He was prostrate in bed from great muscular weakness. Bowels constipated but moved on use of calomel followed by castor oil. Stimulation was used, colon irrigation, rectal nutrition and all supportive measures, but on the fifth day he showed marked signs of respiratory failure and died on the fifth day of his illness. Terminal condition was pulmonary hypostasis, but no consolidation. No post-mortem was allowed.

CASE XIV.—W. D. Male, age 52. Rather corpulent. I had treated him a year before for chronic alcoholism, but in the past year he had been strictly temperate. Called to see him on the second day of his illness. In bed. Temperature (rectal), 97.4. Pulse 84. Respiration 18. Physical examination showed systolic murmur with much hypertrophy, bilateral blepharoptosis, diplopia, unilateral nystagmus of right eye. Slight paralysis of facial muscles of right side. Much difficulty in swallowing and articulating. Could not protrude the tongue or expectorate in a normal ejaculatory manner, much saliva of ropy character. Mind was perfectly clear to the last. All symptoms increased until the ninth day when he died. The last twenty-four hours he was quite cyanotic. No pain in any part of the body. The terminal symptoms were pulmonary hypostasis without consolidation.

Post-mortem examination was made by the County Medical Examiner, assisted by a local physician and myself as recorder. Gross pathology showed about 100 per cent. cardiac hypertrophy, mitral insufficiency, apparent parenchymatous nephritis. Spleen about one-half normal size, soft and friable. Liver cirrhotic, stomach and intestines normal in appearance. Specimens of all organs were sent to the State Department of Health laboratory for further examination. No biological examination was made and "nothing was found."

CASE XV.—P. A. Male, age 18. Pale and anemic in appearance, history of pneumonia following "flu," winter of 1918-1919, patient walked into my office on the second day of his illness, complaining of "dimness of vision and seeing double," vertigo on walking but not on sitting down. Unilateral ptosis of right eye, paralytic symptoms relating to the glossopharyngeal nerve. Quite a blank and dazed expression on his face, which normally was bright and cheerful. Great muscular weakness, pulse sitting 76 and standing 90 not compensating. Temperature 98.2°, respiration 24. No gastric or intestinal symptoms. On the sixth day the diplopia cleared up a little, but all other symptoms continued. There was much salivation. On the tenth day he died. The terminal symptoms related to renal insufficiency, urine was scanty and high colored, normal solids absolutely diminished. At last he was quite comatose. Respiration ceased before the heart ceased to beat.

Cases 13, 14, and 15, were treated in a well ordered hospital and everything done that gave possible hope of good results and comfort to the patients. They were seen by two other consultants; the treatment was rational, *i.e.*, elimination and stimulation, no differences of opinion were expressed as to diagnosis or treatment. They were classic cases of Botulism. Some symptoms in the cases reminded us of methylic alcohol poison but there was no possibility that this was a factor in any of the cases. Neither was there any such possibility in any of the other series of cases in Lowell or Tampa. We also discussed acute bulbar paralysis but the absence of any elevation of temperature and other pathognomonic symptoms dismissed this. Lethargic encephalitis gives some symptoms that occur in botulism but the classic picture *la toute ensemble* of poisoning from the toxin of *Bacillus botulinus* is lacking in any other condition with which I am familiar.

The source of the poison in these last cases is not certainly known, but all ate of a ham which was purchased in the open market in a nearby town. Three of the patients spoke of the ham as having a bad taste. Other people ate of the same ham but no other illness occurred. It is possible that the lower end of the ham was infected and the upper end was not. It is certain that the poisoned patients ate of the small end of the ham.

149 WEST NINETY-THIRD STREET.

THE FEEDING OF NORMAL INFANTS.

BY STAFFORD McLEAN, M.D.,

NEW YORK.

DR. MORSE[1] of Boston has recently published at length his views regarding the feeding of infants during the second year. He says: "Whether or not it has been ursed or fed artificially, a baby, when it is a year old, will be taking, in most instances, whole milk or whole milk with a cereal diluent. If it follows the present fashion, it will almost certainly be receiving orange juice in addition. It will probably be taking some of the simple cereals and perhaps broth and beef juice. If it is being fed properly it will not, in my opinion, be given anything else."

It is admitted that certain normal infants will not tolerate at the beginning of their second year of life a more liberal diet, but in the opinion of others, myself included, the average infant will thrive better upon a more liberal and varied diet. It has been noted that infants fed upon such a diet are stronger, more active, walk earlier, their fontanel closes earlier, dentition is earlier, and they have a better color and musculature.

Let us consider the different article of food constituting a more liberal diet for an artificially fed infant and the reasons for their use.

Orange Juice.—In most instances it is well to begin the administration of orange juice as early as three months, one may commence with one teaspoonful daily one-half hour before the second morning bottle. This daily amount may be increased by one teaspoonful each week. At five to six months of age the infant will be receiving the juice of one orange daily or approximately 2½ ounces. The liberal use of orange juice minimizes the necessity for laxatives so often used in the artificially fed baby to correct constipation. Almost all the milk fed to infants in New York City is pasteurized. Scurvy has frequently been noted in infants fed exclusively on pasteurized milk.[2] Orange juice is one of the richest sources of antiscorbutic vitamine; if begun in small doses and gradually increased, it seems to be well tolerated. Infants six weeks of age have been seen who were given orange juice as a laxative without ill effects.

At the age of nine to twelve months orange juice may be replaced by well strained apple sauce or prune pulp. These substances add more bulk, are more laxative, and have a greater caloric value than orange juice.

The Amount of Milk.—The average artificially fed infant, in the experience of many, thrives better after the sixth month with at least part of his caloric needs supplied by other food than milk. The amount of other food may be increased as age advances. As a rule not more than twenty-eight ounces of milk per day is given and after the tenth

month this amount may be gradually decreased. By the eighteenth month he will usually not need more than twenty to twenty-four ounces per day.

Why is it that an exclusive milk diet for an infant up to twelve months of age is undesirable? Chiefly because of the small amount of iron plus the objection to the large amount of bulk necessary to give the infant sufficient calories. It is probably because cow's milk is low in iron that infants become anemic. Every infant is born with an "iron reserve." If he is breast fed he utilizes the iron present in the mother's milk and apparently maintains a normal balance. The iron reserve plus the amount he receives from the cow's milk may carry him along a varying number of months until he finally becomes anemic. This frequently begins to be noticeable from the eighth to the tenth month and becomes more marked as age advances. At that age or earlier he needs a supply of iron from some other source. A sufficient addition cannot be furnished by increasing his supply of milk.

Cereals.—The feeding of cereals may be advantageously begun about the fifth month, generally in the form of strained oatmeal jelly. Oatmeal has more residue to furnish bulk and helps constipation. If begun in small amounts (a teaspoon daily given just before the second morning bottle) it may be increased at regular intervals so that by the tenth month the infant is receiving two or three level tablespoons twice a day. Infants vary in their ability to handle starch but the majority handle these amounts without difficulty. Some infants under three months of age with a stationary weight have begun to increase in weight upon the addition of raw starch in the form of barley flour. Infants have been encountered in the Out-Patient-Department who were doing well on a milk mixture in which the carbohydrate was furnished (through a mistake in interpreting directions) in the form of 50 grams of raw starch per day.

Eggs.—Dr. Morse does not advise the use of eggs before the eighteenth month, he then gives one-half of an egg once or twice a week and gradually increases the amounts. It has been frequently noted in feeding infants that it is the egg albumin which is difficult for the infant to digest. For this reason the administration of egg is begun by using only the yolk, which is high in iron and in fat soluble vitamine[3] and is not difficult to digest. It may be begun about the sixth month with one-eighth to one-fourth of the pulverized yolk of an egg which has been boiled 20 minutes. This is mixed with the vegetable or cereal and the amount is increased each week until the child is having the whole yolk of a hard boiled egg daily. By the eleventh month he may be given a part of a whole coddled egg and, if it is well tolerated, as it frequently is, he is given the whole egg, generally by the twelfth month. Pulverized egg yolk may often be given as early as the fifth month without causing digestive disturbance.

Is the Simple Diet Sufficiently Nutritious?—It is beginning to be appreciated that to furnish a properly balanced ration for a normal infant over six months of age is not so easy as it was formerly considered. Little is yet known of the vitamine factor, yet certain facts have been established. Uncooked food has certain antiscorbutic properties not possessed by cooked foods, orange juice has more of these properties than milk, and the drying of milk deprives it of some of its antiscorbutic properties. Pasteurization also impairs the vitamines and it has been recently shown that scalding milk is less destructive to the vitamines than boiling for five minutes.[4]

Vegetables.—Infants having a varied diet which includes vegetables begun at the seventh month are generally more active, have a better color, and walk earlier than those who have been given what Dr. Morse calls a "simple diet."

Children fed up to the end of the second year on a diet almost exclusively of milk frequently have a severe degree of secondary anemia, even though the caloric intake has been sufficient. There is quite definite evidence that the iron in milk is inadequate.

If vegetables are steamed as described by Courtney, Fales, and Bartlett,[5] the salts are retained and not lost in the water used for cooking. One may begin at the seventh month with one teaspoon of steamed spinach or carrots given daily before the midday bottle. The daily amount is increased each week so that by the twelfth month the child may be having two to three level tablespoons of vegetables per day.

It is difficult to measure the degree of bone production in infants; but the rate of closure of the anterior fontanel is perhaps our most convenient guide. Most of the textbooks on pediatrics state that closure of the anterior fontanel at eighteen months is the normal average. Infants fed chiefly on milk do have, as a rule, an open fontanel until the sixteenth or eighteenth month; but in infants who are fed a varied diet as outlined, here it has been noted by several, and myself included, that the fontanel in a majority of instances closes between the tenth and fourteenth months. Delayed closure of the anterior fontanel is one of the accepted manifestation of rickets. If the fontanel closes at an earlier age in a normal child fed a varied diet is it not a fair inference that closure at eighteen months is a delayed closure and possibly a rachitic manifestation?

Vitamines.—That there may be another factor, namely vitamines, in the use of vegetables during the first year, which is as important as the salt factor is only now beginning to be appreciated. While it is true that many of the observations regarding the influence of vitamines on growth have been on the smaller animals, enough has been learned to establish certain facts which will have a bearing on the feeding of infants and children.

Osborne and Mendel[6] have found that the "fat soluble vitamine" is richer in spinach leaves than in most of the foods used in the daily ration of man. They also found that as a source of "water soluble" vitamine the quantity of whole wheat, soy beans, dried eggs, or milk solids required to promote normal growth, is approximately twice as large as the quantity of dried spinach needed.

It is interesting to note that the Danish people during the last year of the war were largely deprived of animal fats. The absence of malnutrition among them has been attributed to the liberal use of green vegetables containing fat soluble vitamine.

Osborne[7] has stated that the increase of water soluble vitamine increases the appetite and that in his experiments with rats the vitamines must be increased before increasing the bulk of the diet. It may be possible that the early administration of spinach with its vitamines increases the appetite and is an entering wedge for the increase of solids such as cereals, potato, fruit, and egg.

Does the Fat Child Represent a Healthy Type?—It is admitted that the infant fed according to the method outlined here may not have the deposits of subcutaneous fat which may appear so important. A certain amount of reserve weight is perhaps desirable but many pediatrists are prone to judge the results of feeding entirely by the weight curve and are apt to allow their better judgment to be warped because of this.

The inactivity of the fat infant may tend to increase his body weight and decrease his caloric needs per kilo. Schlossmann and Murchauser[8] emphasize the influence of muscular activity on metabolism, and Howland[4] found a difference of 17.6 and 39 per cent in the heat production between periods of quiet sleep and active struggling and crying. Benedict and Talbot[8] found that an increase of 60 per cent was common from sleep to active exercise. The activity of the wiry type of infant might necessitate a higher caloric intake to compensate for his increased metabolism.

mates the diets of children who have been fed according to the method presented here. This diet has a caloric value of approximately 900 calories which would allow a child weighing 22 pounds over 40 calories per pound. It seems undesirable to adhere too closely to caloric method in calculating the amount of food. The caloric value of food is useful as a check in infant feeding. Many normal infants of one year on a "liberal diet" may progress favorable on 850 calories per day, while other may do better on 900 to 1000.

SURGICAL JAUNDICE.

REPORT OF A CASE OF PRIMARY CARCINOMA OF THE PANCREAS.

BY ROYALE H. FOWLER, M.D., F.A.C.S.,

BROOKLYN, N. Y.

THAT form of non-hepatogenous jaundice due to blocking of the biliary flow between the liver and the duodenum may be properly termed obstructive. Biliary stasis from extra hepatic lesions occurs mechanically from obturation of the lumen of the hepatic or common ducts, from occlusion, the result

*Read before the Medical Society of the County of Kings, January 15, 1918.

of trauma, inflammation or new growth of the walls of these ducts, or from choking off the flow of bile as the result of pressure outside the ducts. Pressure from without may be inflammatory or neoplastic. The differential diagnosis of obstructive jaundice due to primary new growths force a decision between carcinoma of the gall bladder, the common duct or ampulla of Vater, the duodenum or the papilla of Vater and the pancreas or its duct. Carcinoma of the gall bladder is the most common, and carcinoma of the common or pancreatic duct the most rare growth which causes this condition. Carcinoma of the duodenum (the papilla of Vater), the ampulla of Vater and the pancreas occupy intermediate positions with regard to frequency. We are especially interested in primary carcinoma of the pancreas, its pathology and operative treatment by palliative methods. The occurrence of a case of obstructive cholemia due to primary carcinoma of the head of the pancreas stimulated interest in the general subject and in this rare lesion particularly.

A consideration of all the phases and literature of primary carcinoma of the pancreas is out of place in this short paper. It is the most common new growth found in this organ. The combined experience of Park and Segré in about 65,000 post mortems indicates the occurrence of primary carcinoma of the pancreas in about one-half of one per cent.

It is more common in males than in females. Oser analyzed 388 cases with regard to sex. He found about 63 per cent. in men and 37 per cent. in women. Cases of carcinoma of the pancreas have occurred in infancy, childhood, and young adult life. Bohn reports a case at seven months, Kuhn two years, Simon thirteen years, Dutil fourteen years, and Burke twenty-two years.

This growth is most commonly found in the head of the pancreas. Segré has studied 68 cases with reference to position. He found 35 in the head, two in the body, two in the tail and nineteen in which the entire gland was involved. Of Maraillié's 133 cases, 62 were located in the head. Oser's sites of predilection closely approximate those of Segré. Robson and Cammidge found 62 per cent. in the head, 5.5 per cent. in the tail, and 3.5 per cent. in the body. In 29 per cent. the growth was diffuse.

This growth is usually small and circumscribed. In the absence of metastasis it cannot be distinguished by palpation from chronic pancreatitis. When metastasis occurs in the liver, the original focus may be easily overlooked. The character of the cells may determine the origin of the growth. Columnar cells are said to indicate that the tumor springs from duct epithelium. Letulle, however, contends that carcinoma originating in the duct of Wirsung is composed of solid alveoli of spheroidal cells. Ollivier reports a case of spheroidal cells forming solid alveoli, which he believes arose from the duct. Hulst believes that the type described by Ollivier springs from glandular epithelium. The majority are the scirrhus variety. Very cellular types are occasionally found.

No definite connection has been established between the Islands of Langerhans and carcinoma. Tumors presenting very irregular arrangement of their cells, are said to spring from these structures. Ollivier is of the opinion that certain growths reported as primary in the pancreas arise from Brunner's glands in the duodenum. No relationship has been established between chronic pancreatitis and carcinoma. In twenty cases of primary carcinoma of the pancreas, Phillips has observed five instances of calculi in the gall bladder. He believes that gall stones predispose to cancer of the pancreas. Secondary growths in the liver are common.

The clinical picture varies according to the part of the gland involved. The head being the site of predilection, jaundice is common. Obstruction of the pancreatic flow may occur without biliary stasis, if the growth is situated in the body of the gland. Ascites and edema are the result of disturbances of portal circulation. Other neighboring organs, the stomach, duodenum and transverse colon may suffer from invasion and compression. Glycosuria is uncommon. When it occurs it indicates involvement of the Islands of Langerhans.

Methods of establishing anastomosis between the biliary system and the gastro-intestinal tract deserve attention. This has been performed between the gall bladder or the common duct and the stomach or intestine. The operation is indicated in properly chosen, otherwise irremediable cases of obstructive jaundice. Its field is limited. No less authorities than Brewer and Moynihan believe it unjustifiable for cancer of the common duct and pancreas. The latter has placed the mortality at 75 per cent., but this however has given way in recent years to a lessened death rate. Thus Jacobson writing in 1914 estimates the immediate mortality at 23 per cent. The late results in thirteen cases which recovered from operation, showed that life was prolonged in some instances for fourteen months.

Anastomosis between the gall bladder and stomach was first performed by Wikhoff and Angelberger in 1892. There is ample evidence to show that the presence of bile in the stomach causes no discomfort and is not injurious to gastric digestion. Kehr states he has preformed cholecystgastrostomy 62 times. Details are lacking.

As regards the operation of cholecystjejunostomy, Mocquot concluded after experimentation upon dogs that danger of infection of the gall-bladder was slight in those cases in which the anastomotic opening was small and exactly made. He found, however, bacteria in the liver, the gall bladder and ducts. Masse and Radviewski found no evidence of biliary infection in their experimental work on cholecystgastrostomy. Hubicki and Szerszinski found marked infection of the biliary system following cholecystenterostomy. These results were confirmed by Bozzi. In 1914 Wideman concluded that anastomosis between the gall bladder and the stomach was not followed by any immediate interference with gastric motility, though later this occurred to some extent. Wideman believed that digestive disturbances were greater when the gall bladder was anastomised to the intestine.

Mayo Robson's preference for anastomosis between the gall bladder and colon is untenable, for here bile is diverted into the terminal portion of the intestine, where it is least effective. Furthermore, there is greater danger of infection.

The palliative operation of choice is either

cholecystgastrostomy or cholecystduodenostomy. Danger of infection in cholecystduodenostomy, if performed close to the pylorus is no greater than when anastomosis with the stomach is performed. Perin gives perference to cholecystduodenostomy. Inability to approximate the parts without tension or other conditions may make one of the less desirable procedures necessary. In a case reported by Ferguson there was no gall bladder present, so he had to content himself with draining the hepatic duct. The following case forms the basis of my remarks:

Miss M. F., age 37, was seen in consultation with Dr. William J. Cruikshank, July 9, 1917, at which time she gave the following history: On January 2, 1917, the patient complained of heartburn, belching of gas and sour taste in mouth. This was followed a week later by severe epigastric pain, accompanied by vomiting for two days. Pain and vomiting then subsided and jaundice was first noticed. This deepened and has persisted without remission. The stools became clay colored, the urine dark and the skin extremely itching. The latter was the chief source of complaint when first seen. In December, preceding the above by one month, the patient was drowsy and tired easily.

At the age of eleven she had "scarlet fever."

Two years ago she had what was diagnosed as an attack of "grippe." The feet and abdomen became swollen and she was told that she had congested kidneys. This attack lasted five weeks.

Upon examination we found a deeply jaundiced, somewhat emaciated, woman, of medium frame. Skin and scleræ were a deep orange bronze. The abdomen was distended with free fluid. The liver was smooth and enlarged downwards three fingers' breadth below the right costal margin. The gall bladder was not palpable.

At the consultation we agreed that the patient was entitled to exploration in spite of her deep cholemic state and the apparent gloomy prognosis. The family accepted this and operation was undertaken only in the hope of affording palliative relief.

The patient was operated upon July 11. The abdomen was opened through an upper right rectus incision. Free bile stained fluid escaped. The liver was smooth and much enlarged, the gall bladder, the cystic, hepatic and common ducts tremendously dilated. There was a large dilated diverticulum springing from the left side of the fundus of the gall bladder resembling a bifid gall bladder. There was no visible or palpable evidence of malignancy in this viscus, the stomach, duodenum, the liver or the pelvic organs. The gall bladder contained no stones. It was not inflamed. There were no adhesions anywhere. The head of the pancreas was very much enlarged and of stony hardness. The gall bladder was drained.

No tissue was available for removal and microscopic study, hence even our operative diagnosis remained somewhat doubtful. Chronic pancreatitis could not be excluded. This disease, attended with painless, progressive jaundice, enlarged liver and distended gall bladder may mimic cancer very closely. We felt that if cholecystostomy after prolonged drainage of the biliary system resulted in the relief of jaundice, and bile was subsequently observed in the stool, we could be reasonably sure that chronic inflammation of the head of the pancreas had existed.

The patient reacted well, intense itching was relieved in a few days. Convalescence was without complication. The wound healed by primary union except for a small sinus. After six weeks of continued drainage the stools still remained acoholic. (We fed this patient her own bile, though it failed to color her stools). Jaundice subsided somewhat. We then proposed to drain the gall bladder into the intestine to conserve the secretion of the liver, and to eliminate the care of an external biliary fistula. The patient was especially anxious to have this closed. Accordingly on August 25, the scar of the previous operation was excised, the sinus was dissected out and firm adhesions broken up. The stomach, duodenum and other organs were again explored. The gall bladder, ducts and liver were found to be relieved of back pressure and were less dilated and enlarged. The head of the pancreas had not diminished in size. The opening previously made in the gall bladder was sutured and an anastomosis performed between the duodenum and gall bladder, approximation was easy and suture accomplished by means of two rows of chromic catgut.

The patient withstood this operation well. The absence of the slightest post-operative hemorrhage in spite of her intense icterus is worthy of note. There was a slight superficial wound infection. There was no bile leakage. Jaundice continued to diminish. The stools contained bile immediately after operation. The urine showed evidence of nephritis. There was no glucosuria at any time. The feet and ankles became swollen and a mitral murmur was detected at the apex of the heart. The wound granulated rather slowly. The edema of the feet and ankles soon disappeared, and the patient returned to her home. Emaciation and asthenia progressed and the patient died on November 9, 1917. The patient lived less than a year after the disease was manifest, about four months after drainage of the gall bladder and about two months after enterobiliary anastomosis. There is no doubt the last operation contributed greatly to the patient's comfort.

At autopsy we found very dense adhesions about the operative field, especially between the dome of the gall bladder and the anterior abdominal wall where the cholecystostomy had been closed. The liver showed a small secondary metastatic deposit on the surface of the left lobe. Sections at various points showed the same type of growth lying deep in the liver substance. The anastomotic opening between the duodenum and gall bladder was patent, the common, the hepatic and systic ducts were still dilated and about the size of a pencil. The gall bladder had contracted considerably. The head of the pancreas was much enlarged and of stony hardness; the body and tail to a less degree. The pancreatic ducts in the substance of the gland were very much dilated. The common duct was completely choked. The duodenum was somewhat dilated. The papilla of Vater appeared normal. It would not admit a fine probe. The stomach appeared normal except for enlarged glands in the greater and lesser curvatures. Sections were made from the liver, the head and tail of the pancreas and lymphatic glands of the greater curvature.

Dr. E. B. Smith, pathologist to the Methodist Hospital, has furnished the following pathological report: Sections from the head of the pancreas show a malignant neoplasm which may be termed adenocarcinoma in that there is a slight attempt at reproduction of the glandular stype of tissue. For the most part the growth consists of strands of poorly differentiated epithelial cells, minus a basement membrane and supported by loose connective tissue. In places there is an attempt at acinus formation, without basement membrane and usually without formation of a lumen. The individual cells are rather cubical, with large ovoid nuclei, poor in chromatin. Mitotic figures are not numerous. Sections from the tail of the pancreas fail to show carcinoma. Sections from the lpmph nodes and metastasis in liver show a diffused carcinoma.

Conclusion.—1. However certain the diagnosis of malignancy, cases of obstructive jaundice should be explored, especially in view of the mimicry of chronic pancreatitis.

2. Chronic pancreatitis may masquerade even on the operating table.

3. In otherwise irremediable lesions palliative methods of choice consist of some form of biliary anastomosis. Thus prompt relief from itching may be obtained, biliary secretion conserved and the patient's life prolonged.

4. Anastomosis between the gall bladder and stomach or gall bladder and duodenum, are the operations of choice. These may be easily and rapidly performed. They are anatomically and functionally rational and scientific.

280 Jefferson Avenue.

MESENTERIC LYMPHADENITIS.*

By ABRAHAM O. WILENSKY, M.D.

NEW YORK.

THE differential diagnosis of conditions in the right iliac fossa is still based on precarious data inasmuch as the discrimination depends very largely upon accumulated personal experience, often biased by a knowledge of the relative frequency of occurrence of the individual lesions; up to the present time no method of precision has been developed which affords any aid in this direction. In acute cases the difficulties are much more marked.

Cases are constantly being met in which the lesion is centered in the lymph nodes of the mesentery in the general region of the ileocolic junction. The clinical picture of the illness is identical with that of other acute conditions in the lower right abdominal quadrant; these others are much more frequent than the adenopathies and with the purpose of attempting to differentiate and describe the latter this communication is made.

In some of the cases the pathological picture includes a uniform discrete enlargement of the mesenteric glands which, on microscopical examination, show a simple hyperplasia. Clinically the affection has an acute onset with chill, or chilliness, and fever ranging to 102° or 103° F.; with generalized abdominal symptoms rapidly localizing themselves in the right iliac fossa; and with moderate symptoms of intestinal disturbance. The clinical picture is very like that of an acute appendicitis, and in practically all of the cases which I have seen this error has been made in the diagnosis. The character of the physical findings is such as frequently accompany an advanced form of appendical inflammation, and the objective symptoms include distention, rigidity, and well marked tenderness at McBurney's point. All of the cases which I have seen have been operated on under this diagnosis. The notes of the following case illustrate this group:

CASE I.—A ten year old boy had been having abdominal symptoms for two days prior to his admission to the hospital. The illness began suddenly with generalized abdominal cramps, which had the tendency to radiate towards the right iliac fossa; in that locality the pain localized itself after several hours. A dose of castor oil resulted in numerous bowel evacuations but there was no blood, mucus, or other abnormal content in the stools. There was no vomiting at any time. After a while the pain seemed slightly relieved, but, shortly, it returned again with increased severity. There was some chilliness at the onset and at the time of admission to the hospital the temperature had risen to 102° F.

The boy's abdomen was moderately distended. There was some spasm to the right rectus muscle over its lower half but no real rigidity; and at McBurney's point there was moderately well marked tenderness to pressure. No mass was palpable. The physical examination of the rest of the boy's body showed no abnormal findings with the exception of an hypertrophied condition of both tonsils.

Under the diagnosis of an acute appendicitis the abdomen was immediately opened. The appendix showed no macroscopic change. The terminal ileum and caput and ascending colon were also normal. The lymph nodes in the mesentery draining this part of the alimentary canal were, however, enlarged and varied in size from one-fourth to three-fourths of an inch in their largest diameters. The glands were discrete, there was no periadenitis; and none of the glands showed any liquefaction. One of the glands was excised for microscopic examination and the appendix was removed in the usual manner; the abdominal wound was thereafter closed without any intra-abdominal drainage.

On the day after operation the temperature dropped to normal and the symptoms all disappeared. The subsequent convalescence was uneventful.

The interesting points about this case are centered in the clinical history and in the histological picture. The symptoms and signs are those which one finds with the ordinary forms of acute appendicitis. The lymphadenitis which is found is anatomically a simple hyperplasia. The interpretation of the picture is dubious unless one assumes that some infection had entered from the intestinal tract and had been arrested in the appropriate lymphnodes. Such an assumption is not unreasonable and to my mind seems most likely when all things are considered. Additional strength is added to this explanation from the very prompt improvement which followed the appendicectomy in the reported case. Whether or not, in the event the appendix had been allowed to remain undisturbed, any subsequent attack of appendicitis would have occurred is, of course, a matter for conjecture.

In others of the cases the process has evidently advanced further and more extensive pathological changes are found in the nodes; at the time of operation the glands are matted together into a large mass in the midst of which a focus of suppuration frequently is found. The tumefaction is very commonly palpable through the abdominal wall. Pathologically and bacteriologically this is the ordinary pyogenic process and no tubercle bacilli, or tubercle formation, or evidence of any other extraordinary etiological cause is demonstrable. The clinical picture is very similar to that of the cases in the first group, the difference, if any exist, being one of degree and intensity of the manifestations, rather than any other. Complications occur with this form of suppurative mesenteric lymphadenitis, and of these intestinal obstruction occurs most commonly. I have seen the more advanced form of mesenteric lymphadenitis somewhat more frequently than the simple form first described; the reason is, very probably, the relative benignity of the clinical course of many of the cases in the group previously described and the extreme probability of many of the latter subsiding fairly promptly and without medical assistance. All of the patients in both of these groups have been children and infants. Case II is a very good example of this type of case.

CASE II.—A young undernourished boy became ill and the clinical picture resembled very closely that of the first patient. The symptoms were more marked, however; the fever was higher, the patient looked sicker, and in addition to the local abdominal phenomena of spasm, tenderness, and distention, a mass was palpable in the lower abdomen partly in the right iliac fossa and partly extending across the median line to the left. The duration of the illness, which was several days longer than in the previous patient, prompted the assumption that the inflamed appendix was either wrapped in omentum, or was surrounded by an abscess. With this diagnosis the patient was operated upon.

On opening the abdomen the mass was seen to be buried in and under the mesentery and the loops of intestine surrounding it were everywhere non-adherent and distinct from one another. A rapid survey showed that these as well as the appendix were normal in every way. As a preliminary measure the appendix was removed. A further examination of the mass showed that it consisted of a number of lymph nodes

*From the Mount Sinai Hospital, New York.

which had become matted together and had broken down and the presence of pus was demonstrated when during the manipulations the abscess was ruptured into. It was not possible, nor did it seem advisable, to do anything more radical than institute proper drainage. Accordingly this was done and the abdominal wound was sutured with the exception of one angle through which the drainage emerged.

The postoperative course was rather stormy. The temperature persisted for several weeks before it came down to the normal level. The subsequent course of affairs was marked by an attack of acute intestinal obstruction which made its appearance before the abdominal wound had completely healed and for which operation was necessary. The obstruction was due to a broad adhesion in the neighborhood of the old wound and sinus which had produced the sharp angulation of the small intestine. Owing to the precarious condition of the child nothing radical could be done and one had to content one self with establishing a fecal fistula as close to the point of obstruction as possible.

The fecal fistula acted most efficiently in relieving the obstruction and fecal matter continued to discharge from the wound for a number of months. Finally the fistula had to be closed by operation during which the loop was freed from its attachments and the opening was closed and inverted in the usual way. This was followed by prompt healing and soon thereafter the patient was discharged from the hospital cured.

There was no evidence at the primary operation of any tuberculous infection and the observation was later confirmed at both of the secondary operations. The latter corroboration is of great importance inasmuch as if any tuberculous infection were present, it is more than probable that evidences of the latter would have been visible at one or both of the subsequent operations. There were no indications at any time of any tuberculous focus in any other part of the patient's body, especially in the lungs or in the cervical glands.

There can be no doubt that the relationships between the cases illustrated by both of the types described are very intimate; in fact they are surely but different stages of one and the same pyogenic process; but whereas in the first type the process is so benign that resolution occurs and spontaneous cure follows, in the second type the more virulent infection leads to a more advanced pathological process in which suppuration occurs and operation becomes necessary. The portal of entry for the infection is undoubtedly some part of the intestinal tract and it is not demonstrable nor susceptible to any form of preventive or other treatment.

I can remember a number of patients on whom I have operated for large intraperitoneal abscesses of unknown origin and etiology which were located in the lower right quadrant of the abdominal cavity; the primary lesion was not demonstrated at operation for the reason that the abscesses were enormously large and one felt that any undue exploration would endanger the patient's life by an exposure to the risks of a general peritonitis. Up to very recently I have always considered that these were probably appendicular in origin, but since my attention was attracted by my own experiences to these forms of mesenteric lymphadenitis, I have begun to wonder whether some of these abscesses did not have their origins in suppurating glands of the mesenteric space. It is quite probable that if the appendix was the cause for the suppurations, the length of time the abscesses had been present would have been more than enough to allow the appendix to slough completely away in at least a large percentage of the cases; this is the supposition which is generally held. And yet it seems very remarkable to me now why at least some of these did not develop some form of fecal fistula during the course of healing; for spontaneous closure of an appendix stump, or of an opening in the caput, is a very stubborn affair and one whose consummation would take many months during which, at some time or other, some indication of intestinal discharge ought to be visible. The great majority of these have, however, healed very quickly and the healing has been permanent.

The third variety of mesenteric inflammatory lymphadenopathy, which I have encountered, is, of course, the tuberculous infection of the nodes. Cases are included in which the lesion is microscopic and is limited to tubercle formation within the interior of the gland, as well as those with marked periadenitis and abscess formation. The clinical picture shows no demarcating phenomena from the pyogenic variety and in the acute cases the nature of the symptomatology deludes one into the belief that some entirely different lesion is present. It is well known that in children the mesenteric glands can form the primary focus for the infection and it is quite common to find these in the absence of other foci, especially those in the lungs or cervical glands. Tuberculous lesions in other parts of the abdominal cavity, in the intestines or in the peritoneum, are, more commonly than not, not present except when they occur secondarily and probably as a result of contamination during the course of operation. I have seen such a sequence of events when, after an appendicectomy had been done at the primary operation, the infection later apparently involved the appendix stump resulting in its opening and in the formation of a fecal fistula; thereafter the infection passed upwards to the caput and from thence onwards to the ascending colon or backwards to the ileum; usually the form of the resulting pathology is that of the hypertrophic variety of ileocecal tuberculosis and the lesion may be mostly in the mucous coat or limited to the peritoneum. Usually at the secondary operations, which almost always prove necessary, the lesion has not extended beyond the bounds of operability. The notes of the following case serve to illustrate this group:

CASE III.—This was a young girl of 16 years who, similarly to the previous patients, was admitted to the hospital with the diagnosis of acute appendicitis. The history was quite the orthodox one for such an illness and included an acute onset with generalized abdominal pain associated with vomiting and constipation, followed by a fairly rapid subsidence of the general symptoms concomitantly with the localization and intensification of the symptoms—pain, rigidity, and tenderness in the right iliac fossa. There was nothing in the family or previous history to cause one to suspect any unusual etiology; the patient had never been ill before. The general physical examination disclosed no abnormal findings and locally a small mass was palpable which was interpreted as being a much thickened appendix with or without a small accumulation of pus.

Operation was done immediately. On opening the abdomen, however, it was found that the small mass was a group of inflamed glands, buried in the mesentery near the ileocecal junction; these were matted together and contained a soft area; the appendix, although it lay very near, was not involved in the process. Nowhere else in the belly could any other lesion be demonstrated and in the immediate neighborhood there was no indication of a spread of the pathological process either from or to the intestinal tract. The appendix was removed. An attempt was also made to enucleate the glands; this was only partly successful and during

the manipulations the abscess was ruptured and a small quantity of yellowish pus discharged. A drain was inserted and the abdominal wound was partially closed.

A fecal fistula appeared in the second week; it was rather profuse and continued for more than four months in an unchanged condition. The sutured part of the abdominal wound having become infected during the operation, parted later and thereafter the healing proceeded slowly for a number of months until nothing was left but an extremely narrow fistula showing no tendency to close completely; exhausted patience prompted the secondary operation. The cause of the failure to heal as well as of the fecal fistula was known to us from the examination of the lymph node which had been excised at the primary operation.

At the secondary exploration the lesion was found to be of the hypertrophic variety and was located mostly in the caput and ascending colon and to a slight extent in the ileum. The sinus led down to a small opening in the bowel. The intestinal wall was thickened without, however, having any tubercles visible on its surface; but the general appearance of the gross pathology indicated the tuberculous nature of the infection, even if we had had no previous evidence in the microscopical examination of the lymph node. No other lesions being demonstrable in the adjoining coils of gut, the involved ileocecal junction was excised and the continuity of the gut was reestablished by a side-to-side suture anastomosis. The abdominal wound was closed entirely without any drainage having been instituted.

The convalescence was most uneventful and at the end of the second week the patient left the hospital cured.

In the excised specimen the bulk of the lesion lay on the mucosa side. Here there were a number of large and small ulcerations with overhanging edges and showing tendencies to assume vertical directions. There was no stenosis of the lumen even at the ileocecal valve.

These three cases illustrate lesions of lymph nodes which are not at all unusual and which are matters of daily occurrence when the glands are situated in other more accessible regions of the body. The affections are especially common in the lymph nodes of the neck and a lymphadenitis in that locality and of any of the varieties described—simple, suppurative, or tuberculous—calls for no special attention or remark. It has, however, seemed to be of importance to call attention to the fact that similar pathological lesions occur in the abdomen under conditions which bear exactly similar relationships to the alimentary canal that lypmhatic enlargements do in the neck; emphasis is laid upon the occurrence of the simple non-tuberculous forms of lymphadenitis.

Any part of the alimentary canal, the caput or parts of the colon or small intestine, may furnish the portal of entry; or possibly the infection may be transmitted through some pathological formation, such as a diverticulum; at the moment of operation these are usually not demonstrable. The point of entry is, perhaps, most commonly in the appendix. In any case it is probable that the lymphadenoid apparatus of the intestinal wall plays a rôle similar to that which the tonsils do in the cervical variety of lymphadenitis. In the non-tuberculous neck cases that do not go on to suppuration the process, clinically, shows a gradual deferescence; this is to be expected, inasmuch as the primary portal of entry of the infection is not disturbed and the infection is combated by the natural forces. In those of the abdominal variety which I have been privileged to treat all were subjected to operation and an appendicectomy was done; the prompt disappearance of the signs and symptoms which followed the operation may perhaps serve to indicate that the source of the infection was contained within the appendix; and the complete removal of the primary focus explains the difference in the clinical course as regards the more rapid defervescence.

IODOFORM POISONING.

INTOXICATION DUE TO ABSORPTION OF IODOFORM FROM GAUZE PACKING FOLLOWING MASTOID OPERATION; MENINGEAL TYPE OF MODERATE SEVERITY; RECOVERY AFTER PROTRACTED CONVALESENCE.

By MORRIS GROSSMAN, M.D., F.A.C.P.,

NEW YORK.

ADJUNCT VISITING NEUROLOGIST TO THE MOUNT SINAI HOSPITAL, AND TO THE MONTEFIORE HOME AND HOSPITAL.

The incidence of iodoform poisoning has greatly diminished in the past 15 years. On account of its free use previous to that time, many cases in the human subject were available for the study of its toxic action. E. G. Cutler,[1] collected 76 cases and added 2 which he had personally observed. The greater number of these cases (42) occurred in patients on whom the powder alone or crystals of iodoform were used. In 21 cases the powder and iodoform gauze were used in combination. Suppositories and bougies accounted for 7 of the cases. Four cases were due to the use of salve, vaseline, or emulsion, and 2 resulted from the use of pills internally. Thirty-five cases were connected with pathological processes involving bones. The mortality in this group was about 34 per cent. R. E. Gurlach[3] reported 4 cases in 3 of which a severe urticaria-like eruption occurred on the face and extremities. J. C. Josephson[3] reported a case in a 2-weeks-old baby, following the use of an iodoform salve on a circumcision wound. The toxic symptoms appeared in this case within 24 hours. L. D. Borse[4] reports a case of retrobulbar neuritis, resulting in permanent central scotoma, in a man whose burn was being treated with iodoform gauze. He quotes cases by Smith, De Schweinitz, Valude, and Terson, in which amblyopia had occurred after the use of iodoform.

In the mildest form of intoxication the symptoms are chiefly the taste and smell of iodoform; the patient has no desire for food, sleeps poorly, may be a little confused, and is easily excited. In a more severe type, there is complete loss of appetite and no food will be taken. The mental state is altered. The patient may be melancholic and despondent, emotional, excitable, restless, and sleepless. In the most severe type, the patient shows complete apathy, or may be delirious, and may have active hallucinations and delusions. There may be loss of consciousness deepening into coma. The pulse is rapid and the respirations are shallow and sighing.

The symptoms may be preceded by general malaise and then suddenly burst forth. In my case the reaction usually came on about 24 hours after the wound had been dressed. In the most characteristic type of cases the clinical picture closely resembles that of meningitis. The symptoms in the average severe case may summarize as follows: (1) Rise in temperature and pulse rate; (2) Men-

ingeal irritation with mental phenomena, such as irritability, hallucinations, delusions, delirium, stupor, and coma; (3) Marked pallor and emaciation; (4) Weakness and loss of tone in the muscles; (5) Hebetude and sleeplessness; (6) Anorexia, nausea, vomiting, brownish coating of the tongue, with iodoform odor to the breath; (7) A papular or erythematous eruption on the skin; (8) All the symptoms most striking at night.

The following is a report in detail of the case that I have observed:

C. P., æt. 13, Peruvian school girl.

Family History.—Father, mother, and 5 brothers are living and well. One brother died of tuberculosis of the spine. Otherwise negative. *Past History.*—Has lived in the United States 1 year. Since the age of 4 years, has suffered from repeated attacks of purulent otitis media. Measles at the age of 8 years. Many attacks of tonsillitis. Tonsils removed last winter and since then has not had any sore throat.

Present Illness.—About 7 weeks ago patient awoke one morning and found that there was a discharge from her left ear. She had not had any pain or other symptoms referring to her throat or ear previous to that morning. I referred her to Dr. M. J. Ballin who found that the left ear drum had ruptured spontaneously, and that there was a profuse mucopurulent discharge from the left ear. He treated her with irrigations of boric acid solution. The discharge continued, draining freely, but never became thick or markedly purulent. About 5 days later the patient developed pain along the anterior border of the sternomastoid muscle and also had pain when the external ear was touched. There was slight tenderness over the left mastoid bone. Her temperature varied between 99° and 101° (rectal). On the 20th day of her illness the temperature rose to 102.8° and considerable tenderness was elicited over the mastoid. The discharge remained unchanged in character and quantity. Consultation with Dr. F. Whiting resulted in continued conservative treatment. The temperature came down to its previous level and remained so for 10 days. Then, the temperature again rising to 103.6°, and the tenderness over the mastoid becoming more marked, immediate operation was advised by both Drs. Whiting and Ballin. That night the patient was removed to a hospital and operated upon for mastoid disease by Dr. Ballin. At operation the mastoid was found to be spongy, softened, and much congested. No abscess was found. The dura was not exposed. The wound was packed with a strip of iodoform gauze, and the patient was returned to bed in good condition. The next day the temperature rose to 104° and remained at that level for 2 days and then dropped by lysis to 100° where it remained for 3 days. Before the operation the medical and neurological examination was negative. The fundi, cranial nerves, superficial and deep reflexes were all present and normally active. There was no Kernig or Babinski present. The day following the operation a slight bilateral Kernig was noted. On the fifth day the wound was dressed. It was found to be clean, and only very slight discharge was present. Iodoform gauze was again used as packing. About 24 hours later the temperature gradually rose to 103°. There was no chill. The patient became restless and irritable. No focal symptoms were present. The bilateral Kernig became very much more marked. There was no rigidity of the neck. Frontal headache was present. The fundi were normal. The muscles were flabby and the tone was diminished. The deep reflexes at the knee and ankle became markedly diminished. The abdominal reflexes were undisturbed. The patient showed marked pallor and emaciation. The urine, which 3 days previous had been normal, showed a trace of albumen and a few hyaline casts. The blood count showed 4,000,000 red cells, 65 per cent. hemoglobin. No plasmodia were found. The Widal was negative. There were 17,500 white blood cells, 84 per cent. polymorphous and 16 per cent. lymphocytes. Her blood pressure was 80 systolic and 50 diastolic. The temperature remained 103° for about 24 hours and then gradually dropped to 100°. It never reached normal. The pallor became more marked and the patient became emaciated very rapidly. She refused to take any food, but took ice and water constantly. Three days later the wound was dressed again. The next morning the temperature rose to 105°. There was no chill. No focal signs of any kind were present, but the patient complained of pain in the neck on the left side. A blood culture was taken and it proved negative. The parents would not permit a lumbar puncture to be done. The urine showed a large amount of albumin, many hyaline, epithelial, and granular casts, a large number of white blood cells, and a few red blood cells. Neurological examination showed that the fundi and the cranial nerves were normal. No rigidity of the neck, but marked hyperesthesia along the spine. Marked hypotonia and weakness of the muscles of the upper and lower extremities. The abdominal reflexes were diminished, especially on the right side. There was almost complete absence of the knee jerks on both sides, and marked diminution of the ankle jerks on both sides. There was a marked bilateral Kernig present. No Babinski was elicited. The temperature came down by lysis in the next 24 hours, and remained at 100°. The next day the wound was again dressed with iodoform gauze, and once again the temperature rose to 103.6°, and remained so for about 24 hours. The urine and physical signs remained about the same, but the patient's general condition became progressively worse. Lumbar puncture was again refused. The blood count showed 16,000 white blood cells, with 84 per cent. polymorphous cells. The nephritis became more marked. The patient became very irritable, was unable to sleep, and would take only ice and water. She felt nauseated and vomited once. Similar reactions occurred after the next 2 dressings. The patient developed a very unstable mental state. She was sleepless, intensely irritable, and melancholic. She complained to the nurse that she was sure that her abdomen was to be opened in order to remove something, and that she would surely die if she were operated upon again. At times she would mutter to herself. She resented the slightest disturbance, and was on the verge of a maniacal outburst. Her urine output was much diminished, and showed evidence of an intense nephritis. Lumbar puncture was insisted upon and permission was granted. The spinal fluid was under normal pressure. It was clear, and there were no cells. Globulin content was normal. The Wassermann reaction was negative. I had suggested previously the possibility of iodoform intoxication, on account of the reactions after each dressing, but without lumbar puncture true meningitis and meningitis sympathica could not be ruled out with any degree of certainty. The iodoform was immediately replaced with plain gauze. Within 12 hours the temperature dropped from 103.8° to 100° and within 24 hours it was 98.6° by rectum. It has remained normal ever since. The patient became much brighter, less irritable, and more quiet. The Kernig had become less marked, and the knee jerks were obtained on reinforcement the next day. The reaction for iodine was positive in the sputum and remained so for 10 days after the last dressing. Slight reactions were obtained in the urine, but none could be detected in the spinal fluid. The nephritis gradually diminished and after the fifth day only a faint trace of albumin was present in the urine. The desire for food did not return for about 8 days. The nausea continued and the patient vomited for several days after the last dressing. The Kernig was still slightly present on the tenth day. The knee jerks were obtained without reinforcement on the fifth day, but are still subnormal on the tenth day. The abdominal reflexes were normally active on the fifth day. The muscle tone, pallor, and nutrition have greatly improved.

Summary of the Case.—In this patient, rigidity of the neck and cranial nerve palsies were the only features lacking. The Kernig sign appeared 24 hours after the first iodoform packing was introduced. There was still some evidence of it 14 days after the packing had been removed. There were associated with it frontal headache and a hyperesthesia so marked that the patient suffered

agonizing pains with the slightest movement of the body. Active delirium did not develop, but the patient at times was confused and bordering on the point of active hallucinations and delusions. These periods were followed by dullness, apathy, and marked irritability. High fever was present and the pulse rate was correspondingly increased. The tongue was dry and had a brownish coating. Striking pallor and emaciation were present early, and there was marked weakness with hypotonia of the muscles. The deep reflexes were diminished almost to the point of disappearance—the knee jerks more than the ankle jerks. The patient was nauseated and refused all food. Vomiting did not occur until 4 days after the removal of the gauze. A discrete papular eruption appeared.

Comment.—This case is unusually interesting and instructive. Iodoform poisoning from the small amount contained in a strip of 3 or 4 inches of gauze indicated an unusual susceptibility to the drug. Two possible channels of absorption may be considered: (1) From the wound directly; (2) by drainage through the Eustachian tube into the pharynx, and the poison then being swallowed into the stomach. The difficulties in diagnosis are obvious. The possibility of sinus thrombosis, meningitis, and brain abscess complicating operation upon the mastoid had to be carefully considered. Sinus thrombosis was ruled out by the irregular temperature, the absence of chills, the absence of local signs (dilatation of the superficial veins, edema of the eyelids, cyanosis, exophthalmus, and signs of extension into the jugular vein), and the negative blood culture. Brain abscess in the temporal lobe was excluded by the absence of any signs pointing to involvement of the left temporal lobe, as word deafness or sensory aphasia. The absence of any signs pointing to involvement of the pyramidal tracts or the cranial nerves. The normal fundi, the absence of intracranial pressure, and the absence of ataxia, nystagmus, rigidity of the neck, adiadochokinesis, and asynergy made a cerebellar abscess rather unlikely. Septic meningitis could not be ruled out until the spinal fluid was obtained. The normal spinal fluid immediately cleared up that suspicion. The prompt subsidence of the symptoms on the removal of the iodoform gauze, the characteristic protracted convalescence, and the presence of a positive reaction for iodoform in the sputum 12 days after the gauze had been removed point very strongly to the iodoform intoxication as the agent responsible for the symptoms in this case.

With the exception of hyperesthesia, no other sensory disturbances were present at any time. It is difficult to explain the complete absence of the knee jerks. The extreme hypotonia may in part be responsible. Souques,[5] has noted general absence of tendon reflexes in cases with wounds of the cranium involving the meninges. This, he believes, is due to mild infectious meningitis which passed unnoticed, and of which increase in pressure and albumen content in the spinal fluid were the only evidence. The marked Kernig in the presence of extreme hypotonia, is also an unusual phenomenon.

Medicolegal Notes.

Manslaughter in Second Degree Through Culpably Negligent Treatment by Person Unlicensed to Practise.—On appeal from a conviction of manslaughter in the second degree it appeared that the defendant, who was not licensed to practise medicine, administered to the deceased, who was suffering from an attack of grippe bordering on incipient pneumonia, by laying on of hands and offering a prayer or incantations that the power be transferred from the deceased's body to that of the defendant, and also by giving him a brew or concoction made by parching and boiling hog hoofs, and by giving him shortly before death a headache or fever powder containing 3½ grains of acetanilide. The main contention urged by the defendant was that, in view of the fact that from 10 to 40 per cent. of patients suffering from the disease the deceased had when the defendant commenced treating him probably die, despite the very best of medical attention and nursing, it could only be surmised that the treatment administered possibly might have contributed to the deceased's death, and that the evidence of guilt only amounted to a suspicion, and the crime was not proved with that degree of certainty which authorizes a conviction in a criminal cause. The question in the case was held to be not whether the deceased would have lived had he received treatment according to the care and skill usual among good practitioners of any recognized and authorized school, but did the treatment given and applied by the defendant contribute to and result in the deceased's death, and was the defendant grossly ignorant of the manner in which such disease should be treated and culpably negligent of the patient in giving the treatment? There was evidence from which the jury was held authorized reasonably to conclude that the death resulted in the manner charged in the information. Under these circumstances the court refused to set the judgment aside because of insufficient evidence. A person assuming to treat disease is bound to know the nature of the remedies he prescribes and the treatment he adopts, and he is responsible criminally for death resulting to the patient from gross ignorance and culpable negligence in the selection of remedies and the application of the treatment.—Barrow v. State, Oklahoma Court of Appeals, 188 Pac. 351.

Industrial Board Has No Jurisdiction to Determine Physician's Fees Under Contract.—The Indiana Appellate Court holds that the State Workmen's Compensation Act of 1915, Section 65, providing that fees of physicians shall be subject to the approval of the Industrial Board, is not intended to enlarge the authority of the board with reference to the approval of physicians' fees beyond that provided in Section 25 in case of an emergency caused by the employer's failure to provide medical care, and the board has no jurisdiction to pass upon fees of a physician employed by the employer. An employer, generally speaking, may become liable for physician's fees in one of two ways, viz.: (1) By contract, either express or implied, made with the physician; (2) by a physician treating an injured employee when called on to do so under an emergency caused by the employer's failure to provide medical care, or for other good reason. In the first way the employer has an opportunity to protect himself against excessive charges by contract, and even to obtain such services at less than the prevailing charges by special arrangements, but in the latter way liability is imposed upon him by statute, under circumstances in which usually he could not protect himself against excessive charges. In view of this fact, and the well-recognized custom, among at least a portion of the medical profession, to base their charges for services in part on the ability of the one liable therefor to pay, the Legislature evidently intended to make the fees of physicians, where services were rendered in the way last named, subject to the approval of the Industrial Board as provided in said Section 25.—National Car Coupler Co. v. Sullivan, Indiana Appellate Court, 126 N. E. 494.

THE RECRUDESCENCE OF SYMPTOMATOLOGY.

SOME time ago attention was directed to the renewing of interest in clinical research and the study of the patient according to the methods of the "old school" (MEDICAL RECORD, Feb. 28, 1920, pp. 362 and 368). Sir James Mackenzie, to whom, more than to anyone else, perhaps, may be attributed this reawakening of interest in symptomatology, *per se*, again emphasizes the importance of symptoms in medical practice and research (*Edinburgh Medical Journal*, September, 1920, p. 156), and calls attention to the mistaken attitude of the medical profession toward this subject. "Ever since medicine was seriously studied," he declares, "symptoms have received attention, and the notion is firmly held by medical men, specialists, physicians, surgeons, and experts of all kinds, that the symptoms revealed by the doctor's unaided senses are so well understood that the information gathered from them has been exhausted, and that their further study is not necessary to the progress of Medicine; hence has arisen the belief that for the progress of Clinical Medicine new methods are necessary for further elucidation of symptoms."

A frank analysis of the situation thus developed—coincidentally with the evolution of laboratory diagnostic methods—inevitably leads to agreement with this statement, with the conclusion that this mistaken attitude toward symptoms is not only misleading, but hampers both practice and research, and with the charge that the importance of symptoms is so imperfectly realized that an accurate description of the meaning, mechanism, and significance of symptoms is nowhere to be found, which constitutes a great defect in medical knowledge. If one has given little or no special thought to this defect it will come somewhat in the nature of a shock to be told that, putting aside trivial ailments, of the illnesses which lower the health of the great majority of people only a small percentage (5 to 10) are capable of being diagnosed with any degree of accuracy. A further shock will be experienced when this lack of accuracy in diagnosis is translated into terms of health of the community. Sir James has made this translation for us: "In a town of 100,000 inhabitants 25,000 will likely consult doctors in one year. Five thousand may suffer from trivial complaints and accidents. Of the 20,000, only a small proportion will suffer from diseases that are diagnosable, say 2,000. We have, then, in a population of 100,000, 18,000 people ailing, of the nature of whose complaints we are still profoundly ignorant." Comprehension of the significance of these figures, relative though they may be, convinces one that despite all the modern methods of diagnosis much yet remains to be accomplished in this direction.

If, as Sir James Mackenzie avers, most of the five to ten per cent. of cases of diagnosable illness are so advanced that the organs are damaged beyond repair, as in apoplexy, chronic Bright's disease, advanced heart disease, perhaps also consumption and gastric ulcer, while the origin of the ill-health was not detectable, then certainly a recrudescence of symptomatology—a close and intimate study of the patient from the point of view of the mechanism by which the symptoms are produced—is a consummation devoutly to be wished. With this painstaking and analytical study and interpretation of symptoms, with the additional light which may be thrown upon the problem by the various laboratory aids to diagnosis, the percentage of cases and of diseases in which accurate diagnosis at an earlier stage is possible should be raised far above the present scale.

CHANGES OF THE TESTICLE IN TRAUMATIC ORCHITIS.

SPEAKING in a general way, contusion of the testicle presents three degrees, namely, interstitial blood suffusions, hematoma of the testicle, and rupture of the albuginea with hernia of the seminiferous tubules. To effect the latter lesion a pressure of fifty kilograms is required. A certain degree of contusion of the scrotal integuments always exists but suppuration is rare.

Whether or not traumatic orchitis really exists is still a moot subject. Monod and Terrillon have shown that aseptic pricks or cuts of the testicle are followed by only an insignificant reaction, but contusions prove to be much more characteristic inflammatory phenomena, with interstitial edema, proliferation of minute connective tissue trabeculæ enclosing the lobules of glandular tissue, infiltration with leucocytes, dilatation of the vessels, progressive, followed by retrogressive atrophy with ultimate sclerosis of the seminiferous tubules. Some time ago Churchman reported a case of left traumatic orchitis in a young man upon whom he had performed castration, a year after the injury, for a very large varicocele and atrophy of the testicle, but the interest of the case resides in the pathological findings. The testicle was reduced to the size of a filbert but contained a few intact tubules, the majority of which had completely degenerated. The reciprocal independence of the lobules was consequently demonstrated.

Atrophy of the seminiferous tubules occurs quickly in all types of orchitis and a kind of equilibrium becomes established between the caliber of the blood-vessels and that of the seminiferous

tubules, which in the physiological state and at the time of coitus help in the propulsion of the seminal fluid toward the epididymis where the ducts provided with muscle fibres and vibratile cilia assure the further progress toward the urethra. The increase of the intratesticular pressure when exaggerated is made evident by a rather sharp sensitiveness of the gland upon the occasion of the slightest shock.

In the pathological conditions under consideration, the testicular congestion, instead of being temporary, becomes permanent during the entire duration of the inflammation and the resulting hypertension not only acts on the vessels but also on the nerves. It can readily be conceived that if the inflammation be intense and persistent the atrophy of the tubules must increase to such an extent as to become both total and permanent. At the time of the contusion of the testicle the blood escapes into the parenchyma following rupture of the blood-vessels, but cannot escape by a rupture of the albuginea and therefore acts like a mildly septic foreign body, setting up a congestive reaction which results in an increased tension. In these circumstances the spermatic canaliculi become more or less atrophied, according to the degree of the congestion, while the consistency of the testicle increases. The gland being rich in nerve supply, the latter must necessarily be submitted to the same amount of compression as the canaliculi, so that a contusion causes not only the peculiar immediate pain, but a very sharp pain which persists so long as the atrophy of the tubles or narrowing of the blood-vessels has not reduced the tension, or a slow distension of the albuginea has not produced the same result. The solidity of the albuginea, which often protects the testicle against external traumatic agents, with the help of the sliding action of the vaginalis, has in the case of inflammation the ill consequence of causing compression of the gland, and plays an important part in the pathogenesis of atrophy and neuralgia consecutive to orchitis.

Therefore, either atrophy or mere destruction of the seminal cells following trauma can be explained, whether the latter can alone be invoked or a former infection is in play.

EROTIC HALLUCINATIONS.

EROTIC hallucinations occupy an important place in mental disease. They may be extragenital, that is to say, arise through the intermediary of some foreign sense, such as the sight, hearing, smell, or taste; or they are genital in the true sense of the term and directly affect the organs of generation. Erotic hallucinations are frequently closely related to puberty, menstruation, or the menopause, as well as with seminal losses, sexual impotency, malformations, and affections of the genitalia. These are the predisposing causes. Among the most important adjuvant causes are the hypnagogic states of the first sleep and awakening, intensive brooding, etc. This form of hallucination offers an infinite variety of forms and causes divers sensations in the patient, varying from the slightest sensation of contact to voluptuousness or pain which may accompany normal or abnormal sexual acts, pregnancy, or parturition. Patients react variously in relation to these sensations, but all describe what they feel with a characteristic extravagance of detail. For this they employ picturesque expressions and strange neologisms. Some even go so far as to lose the consciousness of their personality and sex.

Erotic hallucinations do not occur with the same characters in the various mental disorders. In the neuroses, hysteria in particular, the hallucinations are quite as frequently extragenital as genital. The sense of sight is the most commonly affected, but it is rare when there is no participation of the other senses. The hallucination takes place in a state or oneirism or subconsciously either during the day or night. Frequently painful, they may be accompanied by voluptuousness and be related by the patient with a luxury of detail capable of imposing reality; they have often served as a starting-point for auto-accusation or slanderous denunciation. Finally, they have a peculiar tendency to extend by contagion. Although uncommon, erotic hallucinations may arise in obsessions. Sometimes, as in a jealous obsession, they occur as nocturnal visual hallucinations in the form of lascivious pictures, having for effect to create or reinforce a fixed idea; at others, the hallucination is diurnal constituted by a kind of material representation or objectivation of the fixed idea itself at the time of the paroxysms. This latter form is especially observed in obsessions of scrupulousness, or as if by a kind of contrast, the most obscene visions appear to the patient at the time of religious devotion. In the systematized insanities, erotic hallucinations are prone to affect all the senses. Those of the sight are less frequent of all and imply an hysteric or alcoholic basis. Those of smell, taste, and especially hearing, are more varied and frequent, and this is likewise true of genital hallucinations properly speaking, in which all possible sensations may be met with. The erotic hallucinations of the delirium of persecution—the type of systematized insanity — are essentially distressing and provoke on the patient's part the characteristic means of defense in the genital form.

Ordinary degenerates rarely have hallucinations, but the hypochondriacal degenerate is rather frequently subject to illusions relating to the genital organs. Among the toxic deliria, the alcoholic form offers erotic hallucinations, especially visual, colored, mobile, multiple, and relates more especially to ideas of jealousy. In the delirium of chloroform or that of hasheesh or from inanition—also a toxic delirium — visual, genital, or extragenital erotic hallucinations may occur and are usually oneiric.

SOURCES OF ERROR IN BLOOD SUGAR ESTIMATION.

THE Lewis-Benedict method for the estimation of glucose in the blood was the first of those methods devised by American investigators, which have made the chemical analysis of the blood a com-

paratively simple procedure and which have so enlarged our information of the body changes in the so-called diseases of metabolism. The method for blood sugar was applied at first chiefly to diabetics but it was soon found that high results were obtained in a number of apparently unrelated conditions. The method has been improved and many studies have been carried out in the attempt to discover the reason for some of these anomalous results. It has been shown that in cases of nephritis in which the blood creatinin is very high, the reading for glucose is increased above that to be expected and it is known that picric acid reacts with creatinin to form a color which may readily be confused with that of solium picramate, the color developed with glucose.

Recently Cowie and Parsons have gone much further in an attempt to find interfering substances (*Archives Int. Med.*, 1920, xxvi., 333). They find that exceedingly small amounts of epinephrin, acetone, or diacetic acid produce decided color changes with the picrate solution used in the sugar method, and suggest that one or more of these substances may be the cause of some of the questionable results obtained. Indeed their results would seem to indicate that the amount of acetone in normal blood may be sufficient to influence the readings as arrived at by this method. It is a fact that the results obtained by Benedict's revised method are somewhat higher than those by the methods of Bang or Folin and it is possible that these authors have discovered the explanation. The reaction with epinephrin also offers an attractive basis for speculation for in many patients who give a high blood sugar there is also present a high blood pressure and the temptation to associate this condition with an increase of epinephrin in the blood is almost irresistible. Unfortunately such patients give high blood sugars with all of the methods at our command and it is necessary to assume that epinephrin reacts similarly with the different reagents used.

It is to be hoped that the work of these authors will be carefully tested and extended, for if well founded it involves a radical rearrangement of our ideas as to the sugar content of the blood not only in diabetes, which is most important, but also in other conditions in which, if not so important for the treatment of the patient, it should contribute largely to a clearer understanding of his chemistry.

THE UNITY OF SCIENCE AND THE UNITY OF MATTER.

"LE TOUT EST UN." One of the most burning questions of today is that of the unity of science. Unfortunately, its study has so far accomplished little beyond the accumulation of data furnished by the experimental method. Most particularly, the atomic constitution of matter — the basis of chemical theory—is an hypothesis the exactitude of which nothing guarantees; it offers no certitude on the subject of phenomena produced, merely indicating those that are possible. Nevertheless, in itself the study of chemical reactions shows the immense utility of the atomic hypothesis. The same study—this hypothesis being admitted—permits profound penetration into the very interior of the chemical molecule. It furnishes extremely precious data on its constitution and on its possible isomers and their number, data which no other procedure has so far been able to obtain. This is an historical truth that is on the way to be forgotten or, at least, to be left aside. Had these data not been obtained the wonderful syntheses—the marvel of organic chemistry—would never have been realized.

To fathom the study of matter, however, the chemist has need of the natural philosopher, while the latter needs the help of the mathematician; and the converse is true. Not one of the sciences is completely independent of the others; all render mutual service, and the exclusion of one would render the other sterile. This shows the importance, both present and future, for the study of the unity of matter and the unity of science, of the great discovery made in 1896, by Henri Becquerel, of the radioactivity in "rare soils," itself a daughter of the memorable verification by Roentgen, in 1895, of a type of physical radiation capable of causing light to penetrate opaque bodies. From the light shed by the work of the Curies, Crookes, Lord Kelvin, Rutherford, Ramsay, and many others on radioactivity found successively in uranium, polonium, radium, thorium, etc., and the mensuration of the penetration and duration of this radioactivity, the scientific horizon has been greatly widened. Atomic disintegration has been revealed, and the successive transformations of metals resulting from the departure of their emanations tend not only to demonstrate the unity of matter, but also to reveal the common origin of energy—in other words, to explain the evolution of the world.

MODERN CARDIOLOGY.

IF Sir James Mackenzie in the conduct of the Institute for Clinical Research which he has established at St. Andrew's in Scotland for the purpose of teaching general practitioners how to detect early symptoms of disease, does no more than to point the way to the correct diagnosis of heart disorders and diseases, he will have deserved well of the medical profession. Perhaps there is no organ of the body concerning which so many gross mistakes are made in diagnosis by the ordinary practitioner as the heart, and while it may be allowed that it requires a considerable amount of training to be an even fairly good cardiologist it is obvious that a colossal amount of ignorance still exists in this direction. Mackenzie and Lewis, among others, have dissipated some of the mists of tradition which obscured the subject, but the light has not reached all the dark corners by any means. The work in this respect in the army disproved this fact, for as Dr. Mather Thomson in the *Dublin Journal of Medical Science* for September, 1920, points out, the casual and careless way men were marked V. D. H. in the British Army was nothing short of criminal. He states that at the time he was in charge of the heart wards of a hospital in Salonica, there was an order that any soldier with a cardiac lesion must be at once transferred to the heart hospital. And

the result was that a medical officer in his ordinary routine examination of a patient would find a murmur or some irregularity, would mark the man V. D. H. or it might be D. A. H., and transfer him. In a great many cases the man himself was not aware of his heart, but now his attention became focused on it, and he believed he had heart disease, and, given a chance, he soon developed breathlessness on exertion and cardiac pain. The majority of these men had sound hearts. In civil life the experience is similar and harm is done in many ways by the inability of the general practitioner, as a rule, to differentiate between organic disease and functional affection of the heart. Although it is perfectly true that instructive skill, the result of experience and judgment, will often solve heart problems, it must be borne in mind that many practitioners do not obtain the experience and that instinctive skill and judgment are innate qualities not possessed by all. But the investigations of workers in this region of medicine, notably, perhaps, Mackenzie and Lewis, and the invention of the electrocardiograph have solved many problems, and rendered the diagnosis of heart affections not only easier, but more certain and precise. The average man can now learn to differentiate between some forms of organic disease and functional disorders of the heart. But he must be taught how to do it.

Metastases of a Basal-Cell Epithelioma.

This highly unusual form of neoplasm is reported in the *Bulletin de la Société de Dermatologie et de Syphiligraphie* for May, 1920. Queyrat gives the autopsy finds and Darier and Civatte the microscopical. One primary growth was seated at the right nostril and subcutaneous nodules developed in a short time; while two months after the growth had been first noted, vague symptoms suggested involvement in the esophagus and mediastinum, and death from cachexia ended the patient's existence in less than three months from the onset of the primary nodule. A carcinosis involved the entire integument, made up of mobile subcutaneous nodules, most numerous on the trunk. The face was spared, aside from a nodule near the external canthus of the left eye. One nodule on the trunk ulcerated. The nose had nearly been destroyed by an exuberant ulcer. There was a carcinosis of the pleura with enlarged lymphnodes in the mediastinum, and the esophagus was as if involved in a primary carcinoma of great extent. So many other structures were the seat of nodules that it is hardly worth while to mention any further lesions. Darier and Civatte did the microscopic work and found that the secondary nodules in the skin showed a structure identical with that of an ordinary tubular basal-cell epithelioma which is primary in the skin—despite the often asserted claim that these cancers never metastasize anywhere. The spinocellular type with pearls may be excluded, as may also mixed forms. But so-called mitochondries were seen, and these are regularly absent from the basal-cell epithelioma. The esophageal growth was regarded as primary and the real source of the metastases, and was likewise of the basal-cell type. The case is unique in literature and no theory can be advanced to account for it.

Nervous Anorexia.

We have here a disease-picture which will waste the victim to the bone and perhaps destroy life; which may readily be confounded with half a dozen deadly organic diseases; yet which, under a correct etiological diagnosis, is readily curable. In the gastroenterological number of *La Médecine* (July, 1920, i, 10), Surmont of Lille sums up the condition as follows: It is common and is progressive in character and naturally makes of the subject a semi-invalid with ultimate confinement in bed. The emaciation may reach an extreme degree and may be attended by a senile appearance, as a result of the shrivelled skin. The breath is fetid and suggests acetonemia, the abdomen is flabby, and constipation exists. The syndrome is naturally that of inanition and need not be further discussed. At least six chronic organic maladies must be excluded before the diagnosis can be made. These are cancer of the stomach, cancer of the esophagus, progressive pernicious anemia, the so-called consumptive diabetes, adrenal insufficiency, and last but not least pulmonary consumption. These maladies having been definitely excluded and the diagnosis made of nervous anorexia it must be ascertained whether the motivation is hysterical, neurasthenic, emotional, or actual mental aberration. The hysterical subject, although she may develop the severest type of the disease, is often a simulator who feeds normally when unobserved. The emotional type due to sustained worry, as in the case of an unfortunate love or business adventure, and the psychotic type seen in melancholia and other psychoses may be passed over here. This leaves the neurasthenic type, which comprises gastric hyperesthesia, sitiophobia, and other conditions, and contrary to the general opinion the author would pay attention to the gastric chemism of these patients in the hope that it might lead to some indication for somatic treatment.

Codliver Oil in Tuberculosis.

Old-time medical men believed and preached that codliver oil was a cure for consumption, and this view was held for many years, in fact, until what may be termed the modern school of bacteriologists arose. Those of this school, who made a special study of the bacteriology of tuberculosis, treated with scorn the time-honored idea of codliver oil exerting a curative effect on tuberculosis. It was stated didactically and dogmatically that codliver oil was a food and nothing more and that all it did was to build up the body and to increase its resisting powers against disease. Anyone who argued to the contrary did not know what he was talking about. However, certain recent experiments appear to show that, after all, the doctors of years gone by were no so very far wrong. Dr. J. C. McWalter in a letter to the *Medical Press and Circular* of Sept. 8, points out that Sir Leonard Rogers and others experimenting on certain oils as regards their influence on cancer, have demonstrated that codliver oil has a specific effect on tubercle and on other acid-fast bacilli, like those of leprosy. But, granting that codliver oil can kill tubercle bacilli, McWalter asks whether it really does get at them in

their snug alveolar retreat. Other recent experiments, however, seem to prove this very point, at least, that oils, when taken by the stomach, find their way into the lung tissue and stimulate defensive cell formation there. In a letter to the same journal for Sept. 15, 1920, Dr. John Knott says that the administration of fat to tuberculosis subjects suggested itself to primitive reasoning, but the victim of that fell disease loathed fats, congenitally, and utterly failed to assimilate them physiologically. Saponification was shown to be an essential step in the digestion of adipose material and codliver oil was found to be the most easily saponifiable. Therefore, the therapeutic effects of codliver oil in the treatment of tuberculosis at the present time seem to be that it probably really has a specific action on the tubercle bacilli, that of course it has a food value, a flesh-forming and thus a fortifying effect, and lastly, that methods have now so diminished its nauseating features that it is amenable to the influence of the gastrointestinal fluids, *i. e.* that it can be digested by the tuberculous with fair facility.

Leanness and Emaciation.

Leanness is congenital, emaciation is acquired and due to some disease. According to Tartière's index the ideal weight of an adult expressed in kilograms should be equal to the decimals of height above the meter. Given the actual height and weight it is therefore easy to compute the degree of spareness or emaciation. Roux considers the two conditions jointly in an article which appears in the gastroenterological number of *La Médecine* (July, 1920, i, 10). In regard to leanness, "once lean always lean," although exceptions occur in which the lean man becomes stout in middle life. The author does not appear to be aware of Goldthwaite's teaching that leanness means an abnormally short intestine and the resulting inability to assimilate food reserves, but he quotes Gigou, who states that the congenitally thin man requires 4,000 daily food calories instead of the normal 3,000, and since he does not for one or another reason receive this number the status agrees practically with the doctrine of the short intestine, which by the way is based on actual measurements. The emaciated man in distinction from the merely lean one may rapidly take on weight when the causes of his malnutrition are removed. There need not be a definite disease to explain emaciation. Thus the plump child may at puberty become thin as a result of rapid growth and for several years or until equilibrium is reached he may present evidences of dilated stomach or visceroptosis. A form of endocrinic motivation is seen in hyperthyroidism. Emaciation from undernourishment may appear under a variety of clinical forms, and without special regard to cause these subjects may often recover their weight under rest in bed and forced feeding with butter, cereals, etc. Unless loss of weight is extreme, protein foods in excess are not indicated. Lack of exercise is antagonized by massage and a certain amount of voluntary exercise is compatible with the rest cure. When these cases of emaciation do not respond to treatment a toxic or psychic factor must be suspected.

News of the Week.

Russian Relief.—According to the annual report of the American Red Cross, fourteen million dollars have been expended by this organization in relief work in Russia. The work was carried on by commissions sent to Siberia, western Russia, southern Russia, and the Baltic States. The commissions operated sanitary trains with a total of 75 cars, equipped with 830 beds, with a capacity of 1,550 patients. Antityphus trains operated by the commissions traveled 10,000 miles, furnishing preventive baths to 105,000 persons, disinfection for 1,000,000, and issuing 500,000 clean garments. It is estimated that millions of men, women, and children were helped. In western Russia much of the work was directed toward aiding more than 250,000 allied soldiers held in prison camps, but food and clothing were supplied to thousands of civilians.

Hoover Food Drafts for Dresden.—An American Relief Administration warehouse is to be opened in Dresden, where Hoover food drafts will be honored.

Vienna Death Rate Increases.—The death rate of children under one year of age in Vienna has increased 40 per cent., according to American Red Cross statistics. The vital statistics for the first half of the year show a large excess of deaths over births.

Nobel Prize Awards.—Dr. Jules Bordet of Brussels has been awarded the Nobel Prize for medicine for 1919, and Prof. August Krough of Copenhagen the same prize for 1920. Dr. Bordet recently established the fact that the union of a toxin with an antitoxin was physical rather than chemical, the toxin's molecule, which is the smaller, being enveloped by the molecule of the antitoxin, which is the larger. He is also part discoverer of the Bordet-Gengon bacillus, a minute ovoid organism supposed to be pathogenic in whooping-cough, and of the Bordet-Gengon phenomenon, a test to determine whether or not serum contains amboceptors or intermediary bodies. Professor Krough is a well-known oceanographer, who proved that alkalinity in sea water is greatly increased by the admixture of land water—a proof confirmed by the experiments of Prof. E. Ruppin in his analysis of the water of the Baltic Sea.

Hospital Dedicated.—Beth Moses Hospital, Brooklyn, equipped with 165 beds, was recently completed, at an expenditure of $400,000, and formally dedicated.

Nurses Strike.—The entire staff of the student nurses at the Oswego (N. Y.) City Hospital went on strike October 29 because one of the nurses had been suspended for infringement of rules. An emergency staff was recruited, so that the patients did not suffer.

Location of Police Hospital.—The proposed five million dollar police hospital is to be located in Brooklyn, opposite the Fine Arts Museum, fronting 750 feet on Eastern Parkway, and extending along Underhill Avenue to Lincoln Place, with 750 feet on Lincoln Place.

Sale of Army Hospital Supplies.—The remaining surplus of bandages and absorbent cotton, purchased for the use of the Army during the war, has been sold to a Boston concern for more than $1,000,-

000. The bandages alone, it is said, represent a quantity sufficient to supply the hospitals and surgeons of the United States with all their needs for at least eighteen months. The Boston firm was the highest of a number of bidders for these items. Included in the sale were 1,000,000 dozen roller and between 2,000,000 and 2,500,000 compressed bandages, and approximately 2,250,000 one-ounce packages of absorbent cotton.

Anatomist Needed.—The United States Civil Service Commission announces an examination for anatomist, to fill, among others, a vacancy in the office of the Surgeon General, Army Medical Museum, Washington, D. C., at $1,600 a year, plus increase granted by Congress of $20.00 a month. Applicants should apply for Form 1312 to the Civil Service Commission, Washington, D. C., or to the Secretary of the local United States Civil Service Board. Receipt of applications closes December 7.

Diseases Under Investigation by the Rockefeller Institute.—The Rockefeller Institute for Medical Research announces that the following conditions will be the subject of special study in this hospital during the coming winter; patients suffering from these diseases will be admitted to the extent of the hospital facilities: Acute lobar pneumonia and other acute pulmonary infections; measles; acute rheumatic fever; cardiac disease; nephritis. Physicians may communicate with the hospital by telephone (Rhinelander 900) or by personal application to the resident physician. An ambulance will be sent promptly when required.

Railroad Accidents.—The Interstate Commerce Commission has issued a statement to the effect that fewer persons were killed on railroads in 1919 than in any year since 1898, and fewer were injured than in any year since 1910. In 1919 a total of 6,978 persons were killed and 149,053 injured, compared with 6,859 killed in 1898, and 119,507 injured in 1910. During 1919, of those killed, 273 were passengers and 2,138 were employees; of those injured 7,456 were passengers and 131,018 were employees.

Alvarenga Prize.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about $250, will be made on July 14, 1921, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but cannot have been published. They must be typewritten, and if written in a language other than English should be accompanied by an English translation, and must be received by the secretary of the college on or before May 1, 1921. Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author. It is a condition of competition that the successful essay or a copy of it shall remain in possession of the college; other essays will be returned upon application within three months after the award. Address John H. Girvin, M.D., Secretary, 19 South Twenty-second Street, Philadelphia, Pa.

The Philadelphia Medical Club tendered a reception on October 15 to Sir Auckland Geddes, British Ambassador and Minister Plenipotentiary.

Dr. Albert P. Francine of Philadelphia has been appointed Chief of Tuberculosis Dispensaries in the Pennsylvania State Board of Health.

Charitable Bequests.—By the will of the late R. Dale Benson of Philadelphia the sum of $5,000 is bequeathed to the Pennsylvania Hospital and a like amount to the Presbyterian Hospital. By the will of the late Ellen A. Yewdall of Philadelphia the sum of $5,000 is bequeathed to the Methodist Hospital.

Medical Society Elections.—The AMERICAN ACADEMY OF OPHTHALMOLOGY AND OTO-LARYNGOLOGY, at its twenty-fifth annual meeting held at Kansas City, Oct. 15, 1920, elected the following officers for the ensuing year: *President*, Dr. Emil Mayer, New York; *First Vice-President*, Dr. John R. Newcomb, Indianapolis, Ind.; *Second Vice-President*, Dr. Robert Ridpath, Philadelphia; *Third Vice-President*, Dr. W. C. Finnoff, Denver, Colo.; *Treasurer*, Dr. Secord H. Lodge, Cleveland, Ohio; *Secretary*, Dr. Luther C. Peter, Philadelphia; *Editor of Transactions*, Dr. Clarence Loeb, Chicago. The next meeting will be held in Philadelphia.

THE FIRST DISTRICT BRANCH OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK, at its annual meeting held in Poughkeepsie, N. Y., elected the following officers for the ensuing two years: *President*, Dr. George A. Leitner, Piermont; *First Vice-President*, Dr. Edward C. Rushmore, Tuxedo; *Second Vice-President*, Dr. John A. Card, Poughkeepsie; *Treasurer*, Dr. J. T. Howell, Newburgh; *Secretary*, Charles Ellery Denison, New York.

Obituary Notes.—Dr. PERCY H. EALER died at Philadelphia on October 17 at the age of forty-two years. He was graduated from Hahnemann Medical College of Philadelphia in the class of 1890.

Dr. EDWIN CORLIES BULLOCK died at Upland, Pa., on October 18 at the age of thirty-seven years. He was graduated from Jefferson Medical College in the class of 1906.

Dr. CHARLES H. GARDNER died of pneumonia at Philadelphia on October 19 at the age of eighty-two years. He was graduated from Bellevue Hospital Medical College in the class of 1868. He served during the Civil War as assistant surgeon to the First Pennsylvania Cavalry.

Dr. CHARLES H. HORNING died of heart disease at Norristown, Pa., on October 21 at the age of fifty-eight years. He was graduated from Hahnemann Medical College of Philadelphia in the class of 1881.

Dr. CHARLES S. KINNEY of Easton, Pa., died October 26 at the age of sixty-six. He was graduated from New York Homeopathic Medical College and Flower Hospital in 1879, specializing in psychiatry. He was a fellow of the American Medico-Psychological Association.

Dr. MAURICE L. RADIN of New York City, his wife and seven-year-old son were found dead in their home on October 28, the result of asphyxiation by the fumes from a broken gas heater. Dr. Radin was forty-nine years of age. He was graduated from the University of Kharkof, Russia, in 1897, specializing in neurology. He was a fellow of the American Medical Association, and of state and local bodies.

Correspondence.

OUR LONDON LETTER

(From Our Own Correspondent)

LONDON, October 8, 1920.

Fever in London.—There has been a sharp increase in the number of fever cases in London. The most recent returns of infectious disease by the Metropolitan Asylums Board and the London Fever Hospital show increases in the number of cases of enteric fever, and diphtheria. There were 16 cases of enteric fever, 2,953 of scarlet fever, and 1,591 of diphtheria in hospital on September 18 last. Officials of the Metropolitan Asylums Board point out that the fever curve always rises about this time of the year, and that while the number of cases at present is higher than in the corresponding period of last year, and considerably higher than during the war years, it is not excessive when compared with the pre-war years. According to the latest available figures there are in the Board's hospitals, 4,935 fever cases, including 3,060 of scarlet fever, and 1,640 of diphtheria. The highest figure of last year was 5,018 on a date in December. It was stated at the Ministry of Health that the upward movement usually reaches its limit late in November, and that this year the rise had occurred more rapidly than last year, but there was no evidence that the epidemic was abnormal. Difficulty is being experienced in the hospitals owing to the great dearth of trained nurses.

America and Postgraduate Medical Study in London.—On several occasions in these letters I have referred to the facilities for postgraduate medical training in London and have pointed out that the Fellowship of Medicine and the allied Post Graduate Association have been making great efforts to establish in London a great medical center, in fact, to make of London the great European medical center. So far as Americans are concerned London is peculiarly well adapted for such a position. She possesses almost unrivalled clinical material, a large number of big general and special hospitals, plenty of physicians and surgeons admirably qualified to teach and a common language. To come to details it may be said that a Fellowship ticket costing four guineas a month entitles the holder to attend the clinical practice, including practical demonstrations and laboratory work at twelve great London hospitals and at twenty-five special hospitals in and near London. *The Fellowship Weekly Bulletin* shows where these demonstrations and classes take place and by whom given. But although London has now the opportunity to step in and take the place fomerly held by Berlin and Vienna as a great medical center, she will not be allowed to do so without a struggle. Already, it is reported here, a committee in Chicago have circularized the physicians of the Middle West, stating that they had organized an excursion for physicians to go to Vienna for study as before the war American physicians were accustomed to go. The committee gave assurances that they had prepared the way for the reception of these physicians in Vienna and that the old-time facilities would be offered. Indeed, every inducement possible was given to persuade American physicians to proceed to Vienna for postgraduate work. The belief seemed to be prevalent that the British Medical faculty do not welcome American students with too great cordiality and that the opportunities for study do not compare favorably with those enjoyed formerly in Vienna and Berlin. It must be borne in mind that the British are not an effusive people and the medical men of London may be and doubtless are more reserved than those of Europe in General and of Vienna in particular. At the same time, their reception of American medical students is warm and genuine and the efforts of the Fellowship of Medicine and Post-Graduate Association for the comfort and instruction of such visitors have been persistent and strenuous. As for the complaint that, while the clinical advantages of London are obvious, the arrangements for gathering knowledge are inferior to those which prevailed in Berlin and Vienna, the answer may be made that the system employed is not inferior but different. The courses in Vienna for postgraduate study are arranged with the convenience of graduate students as the sole end and aim. Human material is not regarded in the same way as in Great Britain. In Vienna the patient is looked upon more as a means by which the student can learn something concerning his or her particular condition and most other points are neglected. In London the student is instructed in the every-day routine of the hospital and he sees and studies patients as he would see and study them in the usual course of events. Postgraduate teaching in Great Britain and in London is developing rapidly and along lines appropriate to the present trend of medicine. For instance, Sir James Mackenzie is giving postgraduate courses at St. Andrew's with the object of teaching general practitioners how to detect the early symptoms of disease and, when diagnosed, how to treat them so that they are prevented from proceeding further. More organization and perhaps greater energy is required in London and in Great Britain to bring postgraduate schemes to full fruition, but this is not to say that these schemes will not be successful, and that the American medical practitioner will not be able to learn much in pleasant and congenial surroundings in London and in other large cities of Great Britain.

Consumptive Ex-Service Men.—The Minister of Pensions has considered the recommendations of the Inter-Departmental Committee on Tuberculosis Sanatoriums for Soldiers and Sailors. As a result, he has decided that men suffering from pulmonary tuberculosis, which is admitted to be attributable to or aggravated by service, and who on conclusion of treatment in a sanatorium, undergo a prescribed course of extended treatment, combined with training in a training colony, shall be granted pension at the 100 per cent rate for six months from the date of leaving the colony, and thereafter at the rate corresponding to the degree of disablement but not less than 50 per cent. throughout the subsequent period of two years. The award will be subject to the condition

that the pensioner presents himself when required in order that the Ministry may be advised as to his condition from time to time and as to the need for further treatment. The arrangement will apply also to the pensioner who is not recommended for a further course in a training colony, the 100 per cent. pension in his case commencing as from the date of his discharge from the sanatorium.

Chair of Industrial Medicine at St. Mary's Hospital, London.—Mention has been made already of the proposal to establish a chair of industrial medicine at St. Mary's Hospital, London. Considerable progress has been made towards the consummation of this idea. Many important representatives of business and medicine have formed themselves into a committee for this purpose. *The Times* has interested itself greatly in the matter and has supported the movement ever since the studies carried out on the health of munition workers revealed the great urgency of a scientific examination and organization of labor power. Industrial medicine is not only the most important branch of preventive medicine but may also be termed the new political economy. Properly carried out it should protect industry from fatigue, either proceeding from long hours of labor or monotonous work, accidents, and disease, by which the worker is deprived of his health, the employer of his output, and the State of its strength. It is almost superfluous to point out that the loss due to these causes is both absolute and progressive: as it is obvious that the man or woman who is mentally and physically wearied cannot produce to his or her full capacity, but is also peculiarly prone to disease or liable to cause an accident. In America there has been a much more prompt appreciation of the value of placing industrial medicine on a scientific and practical basis from the health and economic standpoints, for after all they mean the same thing. It is of the utmost concern to labor and capital alike, that the worker should be healthy and contented, and it is quite plain that if he is not healthy in body and mind he will not be contented. Moreover, the discontented workman is the main cause of the social unrest which is disturbing the world from one end to the other. In America there are six professorships of industrial medicine, and needless to state, these have an educational value with which the training of the medical man cannot compare. It is hoped that the appeal of St. Mary's Hospital will meet with a ready and generous response, and that the establishment of such a chair will act as an incentive to British business and medical men to found departments of this kind in hospitals in all parts of the country. It may be added that the authorities of the above medical school have issued recently a booklet in which the pressing needs of the school and the reasons for making the appeal are set out in logical sequence. The importance of medical education to the country, and the increased cost of modern requirements as regards teachers, accommodation, nursing, laboratories, and equipment are explained in language easily understandable by the outside public, for whom the little book is primarily intended. It is pointed out that while the need for rebuilding the school is urgent, it can be accomplished at a not extravagant cost. It is estimated that with great economy and the use of the existing walls, the expenditure on reconstruction should not exceed £30,000. However, this estimate does not include a block for the pathological institute where the director, Sir Almroth Wright, and his staff still work in laboratories adapted from wards originally intended for midwifery beds. It is proposed to supply more adequate accommodation for the institute and to release these wards, in order that they may be used for their original purpose. It is not out of place to say here, that England has starved her scientific medical research and is only now beginning to recognize her shortsightedness in this respect. Where millions have been given freely for this object in America, thousands have been doled out in this country, and it certainly is a reflection on its rich men that a man of world-wide fame in his particular field as is Sir Almroth Wright should be hampered in the prosecution of his investigations by the lack of money. This is indeed being "penny wise and pound foolish." The erection of a suitable pathological institute at St. Mary's Hospital is estimated to cost £40,000 ($200,000). The rest consists in the endowment of chairs, 1, Industrial Medicine; 2, Hygiene, Public Health and Preventive Medicine, and 3, Pharmacology; and of four scholarships of £250 each a year for promising graduates. The appeal is addressed especially to the heads of great industries and to those interested in medical education in general and in the co-education of men and women, as the continuance of this system at St. Mary's is dependent on the provision of increased accommodation. Mrs. Lloyd George, the wife of the Premier, is taking an active part in furthering the object of the appeal and is receiving donations for the same at the official residence in Downing street.

Medical Men and Miners.—The Central Council for Economic Information states that medical men in the Nottingham and Derbyshire mining areas have given notice terminating their contract with the miners' sick clubs, following on the refusal of their proposals for an annual payment of twenty-six shillings per member a year. Dr. Alfred Cox, Secretary of the British Medical Association, in discussing the question recently, said that "the miner insists on the justice of every worker getting the full value for his work and demands that his own wages should rise almost continuously with the cost of living. It is certainly remarkable that he should show such reluctance to applying the same principle when he has to do the paying." It is certainly extraordinary that although the wages of the working men have risen threefold and even fourfold, they object to giving a fair rate of payment for medical attendance. If they subscribed to the hospitals in proportion to the benefits which they have received and do receive from them, these would be able to continue on a voluntary basis and expend the necessary money in rebuilding and reconstruction. But the workman appears to think that he should receive all and give nothing or as little as possible. The middle class, of which the medi-

cal profession is an essential part, has practically to support the State.

Obituary.—Sir John Byers, M.D., professor of midwifery, gynecology, and diseases of children, Queen's University of Belfast, died suddenly in his sixty-seventh year in Belfast on September 20, last. John William Byers was born in Shanghai in 1853, the son of a China missionary and of Margaret Byers, née Morrow, one of a group of famous women educationists who founded the Victoria College at Belfast. He graduated at Queen's College, Belfast, with the highest honors in 1878 and not long after he commenced to practise in Belfast was appointed physician to the Hospital for Sick Children, holding that position until 1893, when he was appointed professor of midwifery in Queen's College, a post which he held for 16 years. He had also become examiner in obstetric medicine at the Royal University of Ireland. In 1909 he was appointed to the chair of midwifery, gynecology, and diseases of children at Queen's University, which he occupied at the time of his death. Sir John Byers was one of the first to recognize and inculcate the importance of antenatal supervision of motherhood in order to avoid the causes leading to stillbirth or death in the early months of independent existence. He also firmly believed that maternal care was an essential factor in the welfare of the child and was always averse to institutional care as a substitute for home life.

LETTER FROM BELGIUM.

(From Our Own Correspondent.)

LIEGE, October 1, 1920.

The Epidemic of Cattle Plague which broke out in Belgium about the beginning of August seems finally to be on the wane, a result due to the energetic prophylactic measures instituted by the government. The special antipest serum is still being produced. Its preparation requires a considerable time, and moreover in order to produce it we must obtain blood serum from a cured animal which is to be injected into other animals, and animals cured of the cattle plague are in the minority, for at least 98 per cent of the animals attacked succumb. The following are the measures taken by the government in fighting the epidemic: Absolute prohibition of the transport of any animal whatever by railway or otherwise, the herds being strictly immobilized wherever they happened to be at the time; every barn which sheltered or had sheltered a sick or suspect animal was evacuated and disinfected, the animals being destroyed and buried deeply. Severe penalties were imposed on farmers who tried to evade these regulations or were simply negligent in carrying them out. Up to the present time Draconian measures have succeeded in localizing the plague which has not passed beyond the Belgian frontier. France and Belgium took action in common in their scientific warfare against this terrible evil. Dr. Roux, director of the Pasteur Institute of Paris, recently came to Brussels to get in touch with the Belgian scientists and veterinarians in dealing with the epidemic. The antipest serum, which will be furnished by fifty animals now in course of immunization, will be supplied to Belgium and the adjoining departments of France.

International Institute of Anthropology.—During the month of September, 1921, there will be held at Liège the first meeting of the new International Institute of Anthropology. This institute was officially established at Paris on September 14 of this year, at a congress called together by the School of Anthropology of that city. The scientists of the allied nations had been notified on Nov. 5, 1918, to prepare for this new international organization now established. Mr. Fraipont, who conducts the course of anthropology at the University of Liège, was the official representative of the Belgian government at this congress.

Nature and Treatment of Seasickness.—M. P. Nolf, professor of pathology at the University of Liège, delivered a very interesting lecture on this subject before the Royal Academy of Medicine on July 31. According to him seasickness is a vestibular vertigo, but in distinction from many of the forms of vertigo, it is characterized less by a subjective impression of disequilibrium than by various visceral reactions, such as salivation, sweating, nausea, and vomiting. These reactions are the expression of hypertonic condition of the bulbar autonomic nervous system, caused by the vestibular disturbance. By way of treatment, Professor Nolf seeks to diminish the efforts of this hypertonia by the administration of atropine sulphate, and reports very satisfactory results.

3. Intracistern Incision of Salvarsanized Serum in Neuro-Syphilis.—Henry McCusker, after trying various other methods, resorted to cistern puncture with replacement of the fluid by diarsenolized serum. He presents the history of a case, by way of preliminary report, in which the patient suffered no ill after effects. Cadaveric and living experimentations have shown that a needle inserted to a depth of 4 to 5 cm. would enter the cistern and allow over 1 cm. clearage of the medulla. The cistern puncture, he concludes, offers another route of application in the method of therapy in syphilis of the central nervous system. It gets the serum nearer to the seat of the disease, it is easier to accomplish than a spinal tap, and it offers no more danger than rachicentesis.

4. The Diagnosis of Chronic Conditions by the Spinal Reflex System.—Albert C. Geyser, after reviewing some

of the anatomical and physiological facts involved, and discussing the necessary apparatus (high tension faradic coil with not less than five thousand feet in the secondary winding), described the technique of making the diagnosis. The patient is placed in the horizontal posture upon the examination chair or couch; the spine is uppermost and bared. A large felt electrode, not less than 6 by 8 inches square, properly moistened, is placed just above the umbilicus so as to cover the abdominal brain or solar plexus. This pad is attached to the positive end of the coil, while the negative end is attached to an ordinary sponge hand electrode, not over 2 inches square. This examining electrode should be fitted with an interrupting device. The current is turned on from the full length of the winding to about one-half of its possible strength, and the sponge is brought in contact with the cervical region of the patient. The interrupting device is released and the current flows. The patient is now consulted as to the feeling of the current, which must be in no wise disagreeable. The electrode is gently moved up and down the entire length of the spine six or eight times, with moderate pressure. The patient should now tell the examiner if the current is felt more in one spot than in another. If it is not felt anywhere in particular or everywhere alike, the current is increased and the procedure repeated. If the patient shows by wincing that there are some tender spots, these are marked with indelible pencil. The current is stopped, and bright red areas, from the size of a twenty-five cent piece to the size of the palm of the hand appear just where the patient complained of feeling the current. These spots stand out in bold relief upon an otherwise white background. Immediately underneath this red area are located spinal centers which, perhaps, have been for a long time laboring under great stress from the impulses sent there from some abnormal organ. When this hypersensitive area is irritated with the proper kind of current, it responds by an increase in the local blood supply long before the rest of the skin along the spine is even aware of the presence of the irritant. By looking at one's chart, one finds which particular part of the body or which organ is associated with the responsive center, and so one may locate the abnormal or diseased organ which is responsible for the hypersensitiveness of the sympathetic area just tested. Once having located the organ or region, it is not very difficult, by a process of exclusion, to arrive at the correct diagnosis.

7. Gunshot Injuries of the Chest in Civil Practice.—George P. Müller holds that the great majority of chest wounds encountered in civil practice are stab wounds, or gunshot injuries with or without retained missiles, and sometimes with complicating injuries of the heart, mediastinum, diaphragm, or the abdominal organs, particularly the stomach, colon, spleen, or liver. The problem presented is whether to operate in all cases of stab or gunshot wounds of the chest, or whether to wait for the complications of hemorrhage, pneumothorax, or infection to ensue. If it were not for the occurrence of infection one might say that early operation is indicated when there is a rapidly increasing pneumothorax (from a valvelike opening); when the rib has been splintered by the bullet, and the fragments press on the pleura, or have been driven inward; or when the hemothorax is large and seems to be increasing. Late operation is indicated at any time when the pleural cavity appears to be infected, or after six or seven days, when the patient's condition is excellent and he has been well studied, to remove clot or missile. The crux of the situation, however, hinges on the matter of infection. If one waits until the patient is in excellent condition to stand the operation one may lose the opportunity to so cleanse the pleural cavity that aseptic conditions can be established. If one operates immediately in all cases one will lose many patients from shock, and the mortality of the total will rise. Shock must be met first. After discussing various points in the management of these cases the writer warns that while surgery of the chest is well on its way to further development and improvement the tyro must keep his hands off until he has studied the work of the masters of the past and has digested the lessons of the war. While Duval's famous dictum, "the surgery of gunshot wounds of the lungs must be governed by the principles of surgery as applied to any other gunshot wounds," requires a number of exceptions, it is true in the main, and should lead to the point where the chest can be opened as safely as one now opens the abdominal cavity.

5. Methods of Cultivating the Gonococcus and of Testing Germicidal Agents Against It: Preliminary Note.—Swartz and Davis describe the technique as finally evolved. Using this standard method, they tested a large series of drugs in the treatment of gonorrhea, as well as a number of new substances of the mercurochrome series developed in the laboratory of the James Buchanan Brady Urological Institute, Johns Hopkins Hospital, and others not hitherto used in urologic practice. Their results show that some of these new mercurochrome drugs are more effective than any others yet tested, and superior to mercurochrome—220. They also made comparative tests, using *B. coli* and *S. aureus*, which show a somewhat lower germicidal value than by the commonly used techniques. The comparative tests afford a basis on which the relative susceptibility of the gonococcus and other organisms can be calculated.

6. Symptomatology of Spinal Cord Tumors.—Abrahamson and Climenko catalog the signs of extramedullary tumors whose density is greater than that of the cord, discuss the differential diagnosis between extramedullary soft tumors and intramedullary tumors, report nine cases, and outline the signs pointing to the site of the tumor. They hold that progressive spinal cord disease giving level signs and symptoms should be carefully observed and studied. When no distinct level can be established the effect of lumbar puncture should be carefully watched. Xanthochromia of the spinal fluid in level spinal cord progressive affections usually means spinal cord tumors. One should operate only when a level has been established. Probing above and below the suspected site, while useful in many cases, often fails. Operations, frequently by their decompressive effects, help even in intramedullary tumors. The possibility of a soft tumor in atypical level cord lesions must be borne in mind, as these are frequently overlooked.

7. Ipecac Sensitization and Bronchial Asthma.—M. Murray Peshkin reports the case of a pharmacist who showed true anaphylactic bronchial asthma due to the inhalation of powdered ipecac, engrafted on a recurrent seasonal bronchitic. The case demonstrates the importance of making an inquiry into the occupation of asthmatics.

3. On the Clinical Value of Routine Cerebro-Spinal Fluid Examination in the Diagnosis of Nervous Disease.—A. Douglas Bigland presents results obtained during over a year's work on material gathered from the various Liverpool institutions. From his studies he is led to emphasize the following points: (1) That no patient having nervous symptoms, even though there is a clear history of syphilis, should be regarded as a case of neurosyphilis until proved so by cerebrospinal fluid examination. (2) That no case showing signs of organic nerve disease, and in which no suspicion of syphilis is entertained, should be regarded as non-neurosyphilitic until proved so. (3) That no case with signs of organic nerve disease and a positive Wassermann reaction in the blood should be diagnosed as neurosyphilis until the cerebrospinal fluid also has been examined. (4) That no case with signs of organic nerve disease should be regarded as not neurosyphilis merely because his serum Wassermann is negative. (5) In the diagnosis of neurosyphilis by the above methods the combined evidence of all the tests should alone be relied upon. On no account should the diagnosis be made upon the result of one test alone.

5. The Origin of Cancer.—Alexander Paine, director of the Cancer Hospital Research Institute, London, discusses this obscure subject from the clinical standpoint, first briefly reviewing the distribution and clinical features of the disorder, and also the circumstances under which it arises. His opinion is that cancer is not a specific disease due to the activities of a special parasite, but a disordered growth of epithelium caused by various physical or chemical irritants, the most important being the toxins of microorganisms. He considers that the origin of cancer lies in the degeneration of the nobler parts of the cell consequent on damage of its structure. The result of this damage is to disturb the balance of metabolism by impairing the special functions of the cell, and thereby causing persistent overgrowth.

8. The Place of Muscle Re-education in the Treatment of Anterior Poliomyelitis (Infantile Paralysis). Charles Mackay.

6. Subacute Perinephric Abscess of Non-renal Origin.—Zachary Cope calls attention to the fairly common occurrence of perinephric abscess, which is often incorrectly diagnosed in the early stages. As might be expected from anatomical considerations, the majority of abscesses develop posterior to the kidney. Of fourteen perinephric abscesses under his care eight were retro-renal, two were above, three were below, and one was intraperitoneal in front of the kidney. The term subacute is meant to exclude tuberculous infection, which sometimes develops apart from any renal or vertebral focus. The common organism found in the abscess is *Staphylococcus aureus*. Of twelve abscesses in which the nature of the organism was reported upon eight contained the staphylococcus, three a streptococcus and one a bacillus of undetermined nature. The source of the infection is often doubtful, but in general the cases may be referred to two groups: (1) Metastatic cases following a suppurative process elsewhere in the body, especially whitlows, carbuncles, or boils; (2) those associated with or consequent to dysentery or diarrhea. The onset is usually very insidious; occasionally it is more acute. After a variable period during which the patient's general condition depreciates considerably, while the fever continues or increases, definite signs appear either in the abdomen or in the thorax, or in both. It is not usual for the diagnosis to be made until these signs appear. In uncomplicated extraperitoneal perinephric abscess of non-renal origin an excellent prognosis is permissible if skilled surgical assistance is available. Every case treated by the writer recovered, although two or three had reached an extremely debilitated condition before the abscess was detected. In cases of intraperitoneal abscess the prognosis is more doubtful. In the treatment of perinephric abscess incision and drainage are the procedures of choice.

8. The Place of Muscle Re-education in the Treatment of Anterior Poliomyelitis (Infantile Paralysis).—Charles Mackay endeavors to show that each child that survives the first onslaught of infantile paralysis can be assisted to regain muscle power; a few may remain permanent cripples, in spite of every care, but if treatment is begun at once and properly carried out the majority should recover more or less completely. The paralysis is not the disease; it is the obvious sequela. The aim in treatment, therefore, is not the cure of the disease but the restoration of function. This must be begun at once, before postural defects have occurred, or fibrous changes in the essential structures have taken place. Rest must be given immediately; muscle re-education should be attempted as soon as one can be reasonably sure that the inflammatory process has ceased, which may be at the end of the first week. Whatever may be the explanation of the changes in the spinal cord, it is most important for the physician to realize that the muscles, if only they are handled correctly, will show a large percentage of recovery. It is essential that the attempt at muscle work be made under the easiest possible physical conditions; there must be no fatigue, and after attempting to work the muscles must be at once adequately rested in the correct anatomical position. The three cardinal points of treatment to which Mackay directs particular attention are: (1) Anatomical rest; (2) muscle re-education; (3) general care of the patient, particularly as regards warmth of the limbs, light massage for a short period preliminary to the exercises, careful superintendence of the whole life of the child, and the avoidance of fatigue and strain.

Schweizerische medizinische Wochenschrift.

September 9, 1920, l, 37.

Röntgen Therapy of Malignant Growths of the Uterus.—Steiger of the Berne Clinic for Diseases of Women states that their experience in this field is too recent to speak of five-year cures. Cures by surgical means have been shown to be nothing to vaunt, although the operative mortality has been reduced to 10 per cent. The best result is in the case of an elderly woman treated with radiation since 1915, who is now living at the age of 78. Her growth was inoperable from the start, yet thanks to the rays she is able to enjoy good health. In other cases the author can speak of three and two-year cures in which death finally claimed the patients, although their lives were rendered tolerable up to that point. Other cases again are still under treatment. It must be understood that in Switzerland the *x*-ray treatment has not for various reasons made much headway save as a last resort, and largely from inability to get proper installation. Results at Basle have not been encouraging, probably from imperfect technic. The author also discusses the accessory use of the rays in surgical cases, and it appears that the combined use in the recurrent cases gives a greater survival than in cases which were not rayed—thirty months as contrasted with sixteen months.

Technique of Radium Therapy in Cancer of the Uterus.—Bétrix of Geneva gives some results obtained in Beuttner's clinic. In general, they are both encouraging and deceptive. Inoperable cases have been rendered operable in from three to eleven weeks of radium treatment. Many have survived from one and a half to two years—the treatment has not been in vogue longer. The author would never use radium if much cachexia is present. Some adencarcinomas which have resisted radium may be removed with the knife. In cancer of the corpus the operative prognosis is so good that he would not use radium.

Book Reviews.

DIE INDIKATIONEN ZUR KÜNSTLICHEN UNTERBRECHUNG DER SCHWANGERSCHAFT. Von Prof. Dr. G. WINTER, Direktor der Königl. Universitäts-Frauenklinik in Königsberg. Berlin and Vienna: Urban & Schwarzenberg, 1918.

THIS volume comprises 317 pages. The author gives on the title page the names of five of his pupils and associates who assisted him in the preparation of the work, along with that of Prof. E. Meyer who furnished neurological matter. The indications comprise toxicoses of pregnancy, tuberculosis, cardiac and renal affections, diseases of metabolism and the endocrine organs (Graves' disease, diabetes, etc.), functional affections of the nervous system, hepatic diseases, affections of the ovum, affections of the generative apparatus, psychoses, organic nervous affections, blood diseases and even ear disease (otosclerosis). He then enumerates the conditions in which interruption is unwarranted. The work is the most complete of its kind yet undertaken and by reason of its multiple authorship is really a "system" or encyclopedia of its subject.

RADIOGRAPHY IN THE EXAMINATION OF THE LIVER, GALL BLADDER, AND BILE DUCTS. By ROBERT KNOX, M.D. Hon. Radiographer, Kings College Hospital, London, England. St. Louis: C. V. Mosby Company, 1920.

THIS atlas comprises 64 printed pages and the same number of illustrations of which 15 are on separate plates and the balance text figures. There appears to be no artistic reason for this division as the same kind of radiograms figure in both classes. The detached plates simply represent figures which could not be accommodated for lack of space on the text pages. The plan of the work is to cover in succession anatomical consideration, gallstones including investigations on absorption coefficients, radiograph interpretations of stones, examination technique, situation of stones, differential diagnosis, the pathological gall bladder record of cases, résumé of literature and general conclusions.

DIE WURMFORTSATZENTZÜNDUNG. Eiene pathogenetische und histologische Studie mit besonderer Berücksichtigung der Bedeutung der Helmmithen, spesiell der Oxyguren und wichtiger allgemenier Klinische Gesichtspunkte. Von Dr. A. RHEINDORF. Berlin: S. Karger, 1920.

AS the title of this volume implies, the author is a member of that school which attributes to the oxyuris or other worm the production of slight traumatisms in the cavity of the appendix which make infection possible. It has been abundantly shown that the worms themselves or their ova are of common occurrence in the rectal appendix, and it is believed that with proper technique the presence of ova could be shown in a still larger number of cases. The author describes and illustrates the epithelial defects caused by the parasites and the symptoms of the disease in oxyuris carriers. A long section on pathogenesis is followed by a recital of autopsy finds in dead soldiers of the late war. The volume closes with a section on prophylaxis. We do not find an estimate of the percentage of cases of appendicitis due to worms, but this is so large that expulsion of these parasites is the first step in general prophylaxis. We do not know whether ordinary vermicides can reach parasites already within the appendix, therefore prophylaxis directed to the individual must give way to a prophylaxis of the public at large. A positive criterion of the presence of the worm in the cecum and appendix does not exist in the absence of repeated examination of stools for ova. Mass infection is very rare, for appendicitis is essentially sporadic. In case of the latter due apparently to worms santonin was given but when operation became indicated the appendix contained no trace of parasite.

THE USE OF COLLOIDS IN HEALTH AND DISEASE. By ALFRED B. SEARLE. With Foreword by Sir MALCOLM MORRIS, K.C.V.O. New York: E. P. Dutton & Company, 1920.

THIS is an excellent introduction to the study of colloidal chemistry and the use of colloidal metals in therapeutics—a subject regarded with much favor in France and some other countries but one that has been neglected to a great extent here. The colloids are indeed employed here in medicine, but only to a slight extent, colloidal silver in its various preparations and colloidal arsenic being the only ones that have found wide application. It is not generally appreciated that many other colloidal metals and non-metallic elements —iron, mercury, antimony, manganese, gold, iodine, sulphur—can be employed with profit in a number of diseases; colloidal iron, for example, being destructive to typhoid and colon bacilli, many pyogenic cocci, and especially to the catarrh-causing organisms in the nose and throat, and being also the most available form for the intravenous, intramuscular, or gastric administration of iron in anemia and chlorosis. Colloidal manganese has been found almost specific in the treatment of boils and carbuncles, succeeeding often in cutting short a series of carbuncles or boils after vaccines have failed, and has also given remarkable results in other coccogenic skin diseases such as acne and impetigo.

Much knowledge of colloids in general as well as of those employed therapeutically may be gained from a study of this book, and the knowledge so gained will well repay the labor.

THE DEVELOPMENT OF THE HUMAN BODY. A Manual of Human Embryology. By J. PLAYFAIR MCMURRICH, A.M., Ph.D., LL.D., Professor of Anatomy in the University of Toronto; Formerly Professor of Anatomy in the University of Michigan. Sixth Edition, Revised and Enlarged. Philadelphia: P. Blakiston's Son & Co., 1920.

THIS new edition of McMurrich's Embryology will give pleasure to many students as well as general practitioners and others whose knowledge of intrauterine development has grown musty and who need a small manual to which they can turn for refreshment of their memory regarding any special point. The book, in its previous editions, has been found useful by a large number of readers, and the reception of this new edition will doubtless be as cordial as before. The book is indeed an excellent epitome of this interesting subject and deserves a welcome from old and new friends.

DIAGNOSTISCHER LEITFADEN FÜR SEKRET- UND BLUTUNTERSUCHUNGEN (Theoretisches und Praktisches). Von Dr. C. S. ENGEL, Sanitätsrat, Arzt und Laboratoriumsleiter in Berlin. Zweite Auflage. Leipzig: Georg Thieme, 1920.

THE author has endeavored to cover, in the brief space of about three hundred pages, the subject of what we know as clinical pathology in so far as it may be carried out by the physician who has not access to a large laboratory. In addition there is a certain amount of bacteriologic discussion with some staining methods. The matter is greatly condensed and all of the more complicated procedures, such as those of blood chemistry have been omitted. This condensation has been carried so far that the subject of the study of the functional power of the kidney is dismissed in a short paragraph with the comment that the methods are too time-consuming and unsafe for the use of the physician. The result is that the book is largely a manual which might be of value for refreshing the memory for some especial occasion. Its value is probably less than that of any of our well-known text-books upon diagnostic methods.

CUNNINGHAM'S MANUAL OF PRACTICAL ANATOMY. Revised and Edited by ARTHUR ROBINSON, Professor of Anatomy in the University of Edinburgh. Seventh Edition. Volume Third. Head and Neck. With 233 illustrations, many of which are colored. New York: William Wood and Company; Elinburgh, Glasgow, and London: Henry Frowde and Hodder and Stoughton, 1920.

THE previous volumes of this new revision of a standard work were noticed in the MEDICAL RECORD of July 31 and August 14. The present volume contains an account of the anatomy and dissection of the head and neck. The text seems to have undergone considerable revision, and much of the description of the dissections has been rewritten. There are many new illustrations, and the book is likely to remain, what it has long been, the standard work on the subject. Medical students and practitioners will make no mistake in including these volumes among their working books.

THE FACULTY OF THE COLLEGE OF PHYSICIANS & SURGEONS, COLUMBIA UNIVERSITY IN THE CITY OF NEW YORK. Twenty-four Portraits by DORIS U. JAEGER. With a Foreword by SAMUEL W. LAMBERT, M.D., A.B., A.M., PH.B. New York: Paul B. Hoeber, 1919.

THIS collection consists of a series of portrait photographs of the more prominent members of the faculty of the College of Physicians and Surgeons during the past ten years. The frontispiece, appropriately enough, is a photograph of the entrance to the College. The group of men here depicted shows well the transitional nature of the present conditions at the college including, as it does, the emeritus professors Jacobi, Weir, Prudden, and Starr, and the more recent appointees such as Hibbs, Squier, and Jobling. The work is really beautifully done and the book will have a definite historical value. The Foreword points out that similar publications have been issued by the College on two occasions, in 1846 and in 1875. The present volume will have as much interest for the future student as the old lithographs have for the physician of to-day. For the graduate of the College there is the additional attraction that the book contains the photographs of the principal teachers under whom he has worked.

EDUCATION IN WAR AND PEACE. By STEWART PATON, M.D., Lecturer in Neurobiology, Princeton University; Lecturer in Psychiatry, Columbia University; President Eugenics Research Association, New York; Paul B. Hoeber, 1920.

IF "peace hath its victories" it necessarily has its conflicts, particularly at a time of such a tremendously general readjustment as must by ordinary follow such a cataclysm as the Great War. The author indicates the signs of the times in such manifestations of public interest in matters that may be termed psychic rather than physical as Spiritualism, Occultism, Christian Science, etc., and hints more than broadly that the physician would do well to recognize this tendency and utilize it for a better understanding of his maladjusted patients. These indications of the public's awakening interest in the problems of human behavior, says Paton, should be evaluated by the physician and both he and his patients led through them to a better understanding of the sources of psychic trouble. In short, he pleads for an approach to the study of feeling and thinking that shall be on a plane in intelligence and interest with the work done in approaching maladjustments of say the circulatory or respiratory apparatus.

Nor does the general practitioner alone come in for Paton's constructive criticism:—it is pointed out that the psychologist is too often so exiguously equipped in the physical sphere that he overlooks important connections between physical and mental hygiene. Some day, however, we shall come, says the author, to such an intelligent and systematic study of personality that we shall test the fitness of a President to rule over us with the same care we now apply to an aviator before permitting him to fly.

Paton, as intimated above, offers constructive suggestions for the problem in hand. These are well worthy the careful attention of the physician, the social worker, the legislator, and others dealing with human reactions and adjustments. To all such this little volume is recommended.

DIAGNOSIS AND TREATMENT OF BRAIN INJURIES, WITH AND WITHOUT A FRACTURE OF THE SKULL. By WILLIAM SHARPE, M.D., Professor of Neurologic Surgery, New York Policlinic Medical School and Hospital; Consulting Neurologic Surgeon, Manhattan Eye and Ear Hospital. Hospital for Ruptured and Crippled, Beth Israel Hospital, New York City, and Nassau Hospital, Mineola, L. I. Philadelphia and London: J. B. Lippincott Company, 1920.

NEUROLOGICAL surgery is a division of neurology or of surgery of comparatively recent development, and, though, of course, general surgery has always had fractured skulls to patch up, it has dealt very gingerly, or ignored entirely, brain injuries unconnected with fracture. In this work the author has divided his subject according to the age of the patients into brain injuries in adults and those in newborn infants and children, the subject being further subdivided under each head into acute and chronic injuries.

A very important section, and the one of greatest interest for the reader who is not steeped in the literature of the subject is that detailing recent advances in the diagnosis and treatment of brain injuries. It is not given to every one to acquire skill in the operative surgery of the brain, but every general practitioner, every country physician, and especially every one in medical charge of an industrial establishment should be able to diagnose the presence of a brain injury whether a fracture of the cranium is present or not.

Of considerable interest also to the general practitioner and to the obstetrician is the section on brain injuries in newborn babies and children.

A large portion of the book is taken up with case reports illustrating the various injuries discussed. The pictures, many of them *x*-rays, are well executed and well reproduced and serve to clarify the text. All in all Dr. Sharpe has made a valuable contribution to the literature of intracranial surgery and his book is one that will appeal to medical readers who are neither surgeons nor neurologists.

PLASTIC SURGERY OF THE FACE BASED ON SELECTED CASES OF WAR INJURIES OF THE FACE INCLUDING BURNS. With Original Illustrations. By H. D. GILLIES, C.B.E., F.R.C.S., Major, R.A.M.C. Surgical Specialist to the Queen's Hospital, Sidcup; Surgeon in Charge of the Department for Plastic Surgery, and Late Surgeon in charge of the Ear, Nose and Throat Department, Prince of Wales's Hospital, Tottenham; Late Chief Clinical Assistant, Throat Department, St. Bartholomew's Hospital; Hon. Fellow, National Dental Society of America. With a chapter of the PROSTHETIC PROBLEMS of PLASTIC SURGERY. By CAPT. W. KELSEY FRY, M.C., R.A.M.C., Senior Dental Surgeon, Queen's Hospital, Sidcup; Demonstrator and Dental Officer in charge of the Prosthetic and Metallurgical Department, Guy's Hospital, and REMARKS ON ANÆSTHESIA. By CAPT. R. WADE, R.A.M.C., Late Senior Anæsthetist, Queen's Hospital; Assistant Anæsthetist, St. Bartholomew's Hospital; Anæsthetist, Great Northern Central Hospital. New York: Oxford Medical Press, American Branch, 1920.

ONE must agree with W. Arbuthnot Lane, who contributes the introduction to this Oxford Medical Publications volume, in congratulating the publishers on the excellent manner in which the task is executed. The descriptive matter, the 844 illustrations of the various procedures and the results obtained by their employment, and the large number of case histories, serve as an excellent basis for the application of war surgery to civil practice. The first of the eight chapters deals with the principles involved, discussed in the order of their application in a given case—history; examination; early treatment; planning the repair (lining membrane, contour and supports, covering tissues); anesthesia (a highly specialized procedure); operation (general technique, stages, suture, dressings, after treatment). The successive chapters, respectively, deal with repair of the cheek; injuries of the upper lip; injuries of the lower lip and chin; prosthetic appliances in relation to plastic surgery; injuries of the nose; injuries in the region of the eyes, including burns of the face, injuries of the pinna; plastic surgery in civil cases. In the last chapter the author expresses the belief that the application of the methods described will have considerable effect upon the possibilities of plastic surgery in the civil community. Apart from the much wider field of deformities which will be brought into the class in which restoration can be applied, the treatment of the disease itself, in addition to the deformity caused by the disease or injury, may be modified. He states, in substantiation of this, that when it is demonstrated that successful and cosmetic rhinoplasty is an operation that can be counted on with reasonable certainty, the early treatment of lupus may be modified in the direction of complete excision of the affected area regardless of the deformity so caused. Should this suggested line of treatment be practical in removing the disease, years of local therapy will be dispensed with. Among the many possible applications suggested, prenatal disease offers a vast field. Thus ectopia vesicæ, hypospadias, meningocele, imperforate anus, and various forms of fistulæ offer scope for the application of these principles in combination.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 7, 1920.

THE FIRST VICE-PRESIDENT, D. JOHN A. HARTWELL, IN THE CHAIR.

THE program of the evening was arranged in co-operation with the Urological Section.

Present Methods for Limiting Venereal Infection.—Colonel C. C. PIERCE, Acting Surgeon General, United States Public Health Service, and Chief of the Venereal Bureau, Washington, D. C., made this presentation, which was illustrated by motion pictures. He pointed out that the venereal disease problem was complex and intimately associated with other difficult problems. The effort of the Public Health Service during the past two years had not been the immediate eradication of venereal disease, which was obviously impossible, but had been to cooperate with the state boards of health in the limiting of venereal infections. The problem had been attacked with combined State and Federal forces from as many angles as possible, in the belief that in this way venereal disease might best be brought under control. It was evident, for instance, that gonorrhea and syphilis could not be fought in the same way as smallpox. It seemed, consequently, that the common sense way of dealing with the problem from the public health standpoint was to render those already diseased noninfectious as far as possible by seeing that proper treatment was readily obtainable; and by dint of legal and educational measures to lessen the number of contacts, at the same time awakening the general public to the dangers of venereal diseases and the necessity for avoiding exposure and securing prompt treatment, when infection had taken place. Before the creation of the Division of Venereal Diseases of the United States Public Health Service, through the passage by Congress, July, 1918, of the Chamberlain-Kahn bill, there had been no national effort to combat venereal diseases in the United States. Up to that time knowledge of the extent of venereal infection was limited to physicians and utterly unappreciated by the general public. A large proportion of the population relied upon quacks and patent medicines for treatment, thus remaining uncured and spreading the disease broadcast. Venereal diseases, except in a few localities, as New York City, for instance, were not reportable, and there was no means of estimating the incidence of venereal disease among the general population of the United States, although there were data on a number of different classes of the population, such as hospital patients, criminals, inmates of insane asylums, etc. The war brought the prevalence of gonorrhea and syphilis among the young men of the country into startling prominence. It was now a matter of history that 3 per cent. of the first million draftees whose examination blanks first reached the Adjutant General's office in Washington had venereal disease when they reported at camp. Of the second million 5.4 per cent. had a venereal disease at the time of their examination upon arrival at camp. This percentage included only obvious cases of syphilis, gonorrhea, and chancroid. Since Wassermann examinations were not given and no effort was made to secure urethral smears, the actual number of cases of venereal infection was undoubtedly much higher than reported. Since the creation of the Division of Venereal Diseases a determined effort had been made to secure the reporting of venereal disease to the State health officers and thence to the United States Public Health Service. It was felt that the first step toward the cure of these diseases was knowledge of the extent and distribution of infections. Therefore, one of the conditions under which each state received its portion of the Chamberlain-Kahn funds was the existence of a reporting law. For two years now monthly reports from all states participating in the fund had been received, and these figures were available. It was not claimed that these figures showed the extent of veneral disease in the United States, because all persons infected with such a disease did not go to physician for treatment, and because all physicians had not yet been brought to a realization of the importance of reporting. What the figures did show definitely, however, was that progress had been made in this direction during the past two years, and that these figures might be expected in time to give a true picture of conditions. In 1919 there were reported to the state boards of health 131,193 cases of gonorrhea, 100,466 cases of syphilis, 7843 cases of chancroid, and others, or a total of 239,502 cases of venereal disease. In 1920 there were reported to the state boards of health 172,387 cases of gonorrhea, 142,869 cases of syphilis, 10,861 cases of chancroid, and others, or a total of 326,117 cases of venereal disease. In other words, the total increase during the past year had been 88,615 cases, or 36 per cent. The relative increase of the cases of gonorrhea reported was 31 per cent. and of syphilis 42 per cent. As gonorrhea was estimated as from two to four times as prevalent as syphilis, a rough check could thus be kept on the finality of reporting figures. Not until the number of cases of gonorrhea reported at least doubled those of syphilis could the reports be relied upon as showing even approximately the true incidence of venereal disease in the United States. After securing the reporting of cases of venereal disease the next step in limiting venereal infection was necessarily making available proper treatment to all those who were infected. The establishment of clinics where reliable treatment could be obtained at small cost or free of charge for those unable to pay was believed to be the way in which to cope with this difficulty. The establishment of such clinics throughout the United States had therefore been promoted. In 1919 there were 237 clinics operating under the joint auspices of state boards of health and the United States Public Health Service, and 167 regularly reported their activities. In 1920 there were 427 clinics operating under state boards of health and the United States Public Health Service and 383 clinics regularly reported their activities. It could be stated that there was practically a 100 per cent. increase in clinic facilities throughout the United States during the past year. There was also an increase of 100 per cent. in the clinics reporting. Clinic reports showed that twice as many patients received treatment in 1920 as in 1919, there being 126,131 patients admitted in 1920 as against 59,192 admitted in 1919. The figures also showed that the treatment was becoming progressively more efficient, for while 6922 patients were discharged as noninfectious in 1919, 34,215 were discharged as noninfectious in 1920. While the number of patients was doubled the number of treatments had been tripled. Nearly three times as many Wassermann tests were made in 1920 as in 1919, and nearly twice as many microscopical examinations for the gonococcus, showing that laboratory facilities were being used more and more by physicians as well as in the clinics themselves. State boards of health reported 328,382 doses of arsphenamine distributed to physicians, hospitals and clinics during 1920, this being an increase of 186 per cent. over 1919. Other medical activities had been campaigns to secure the cooperation of physicians and dentists, and a special course for graduate nurses given at Columbia University in order to fit them for venereal control work. The cornerstone of the medical work was the clinics. These were rated under the following heads: location, equipment, sterilization, histories, records of treatment, use of distilled water, personnel, salaries, treatment, clinic days and hours, daily average attendance, laboratory facilities, fees charged, method of building up clinic, average monthly cost of operation and per capita cost of treatment. A survey showed that in 325 clinics, or 90 per cent., the treatment for gonorrhea was efficient, and that in 337 clinics, or 93 per cent., the treatment for syphilis was efficient. The per capita cost of treatment was under $2 in 80 per cent. of the clinics. After quoting other statistics in connection with the clinics the essayist said it was hoped that the clinics might be brought to conform to a high standard of efficiency, so that any man or woman in the United States who was infected with venereal disease might go to a free clinic and be absolutely sure of obtaining the treatment that was considered most effective by the best medical authorities of the country. In considering the legal side of the question Colonel Pierce said that the first care of the legal section was of

course to see that as many states as possible secured their portion of the Chamberlain-Kahn fund. Further work of the legal division consisted in fostering the passage of state laws and city ordinances having for their aim the control of venereal disease, and in urging the enforcement of laws that had been passed. The character of the legislation adopted by the states varied. Model laws and ordinances that had been found serviceable had been drawn up and had been available to states and cities, and many had taken advantage of these forms and modeled legislation by them. The legal section had as its aim largely to aid the various states in the suppression of commercialized prostitution, as this was undoubtedly the most important focus for spreading venereal disease. The aim of the educational section was to disseminate sex instruction among the public and to bring before the people the knowledge of the dangers of venereal disease and the importance of prompt and efficient treatment. The educational activities had included the publication of pamphlets on various phases of sex education and hygiene, and advice to those infected with venereal disease. In 1919 more than 14,000,000 pamphlets were distributed in response to requests; in 1920 more than eight million. The decrease was due to the fact that these activities were being shared more and more by state boards of health. Other educational activities included posters, placards, lectures, etc. In concluding Colonel Pierce expressed the opinion that through this educational work the ignorance of the public on the subject of venereal disease was being gradually dispelled. At the same time the various cities were ridding themselves of commercialized prostitution, through realization of the danger caused by it to the health of the community. Lantern slides illustrated the various pamphlets, placards, and other educational work, and several motion picture films demonstrated the methods of diagnosis and the technique of treating these diseases.

Dr. EDWARD L. KEYES, JR., said he had come to listen and not to discuss Colonel Pierce's remarks. The paper was one of such cold, hard facts that it did not lend itself to discussion. The facts were given, and there they were. Personally, he had taken an interest in the social hygiene movement ever since its inception by Dr. Prince A. Morrow, and was greatly impressed by the steady progress of the movement toward nationalization ever since its beginning fifteen years ago. The movement was spreading in the national consciousness as a result of the facts brought out during the war. At the bottom of the work now being done was that of the Interdepartmental Social Hygiene Board. As a result of that work one now saw the really systematic effort of the Public Health Service spreading all over the United States. He agreed with Colonel Pierce in the belief that the movement would be a success. It was feared at first that the private practitioner would be harmed by these more or less free clinics, but, on the contrary, the men who were acting as agents for the Government had been upbraided by physicians for having flooded them with cases of venereal disease that previously would not have been treated. Now the Public Health Service had the approval of the medical profession in this movement. Furthermore, in order to get effective action it was necessary to have the enthusiastic cooperation of the medical profession in order to carry forward this movement started by Dr. Morrow, continued by Dr. Snow, and now carried forward by Colonel Pierce.

Mr. HOMER FOLKS, secretary of the State Charities Aid Association, said that just as it was true that epidemics awakened the health authorities and created among the people a state of mind that opened the public purse, so in the same sense war had had one good result. As a member of the council of the New York State Board of Health, Mr. Folks said he could recall when they had looked forward to a time, far in the future, toward the millennium, when very gently, unobtrusively, and without attracting much attention, they might endeavor to do something in the prevention of venereal disease. Now, after an absence of two years, he found a division of venereal diseases in the State Board of Health, and one of the largest, most efficient and best organized divisions in the Department of Health. In matters of public health they had had a great deal of difficulty in getting the right kind of adjustment between local and state health authorities and between State and Federal health authorities, and a great deal of work had been done at cross purposes. It had seemed difficult to see how it could be worked out to get efficient cooperation. This cooperation, however, had been accomplished, and the local, State and Federal authorities were working most harmoniously, most efficiently and effectively. Speaking from the point of view of the layman, when he was asked to take part in the discussion and considered what he should say, the first thought that came to him was that there were various kinds of laymen. Laymen might be divided into four categories in connection with the subject under consideration: (1) Those who had one of the diseases in question. (2) The average citizens. (3) The leading citizens. (4) A small group of laymen or social workers, those working with the public health agencies along this or kindred lines. In the first class results had shown very clearly that it was not difficult to secure patients for treatment, and dealing with them was not a difficult thing. It required only two things: First, they should be made to understand that everything was really confidential and that they would not be exposed to their fellowmen—a point, perhaps, that had not been sufficiently stressed. Second, they must be made to understand that the cost would be moderate. Then the treatment of this class gave a golden opportunity to impress upon them the seriousness of their condition and that their position laid a great responsibility upon them for the protection of others. They must be followed up to see that something was really done about it. The physician could not accomplish what should be done without having these patients followed up by a nurse or social worker. The average citizen did not need to know a terrible lot about venereal disease. The thing he should have was a certain amount of general conviction drafted into his habitual attitude, emphasizing the seriousness of venereal infection, and that if he continued to live a life of promiscuous relations he would contract such a disease almost to a certainty. Beyond this is was not necessary that he should know all the horrible details, but he must have the fact of the seriousness of these diseases lodged permanently in his consciousness. Then, too, he must know that something could be done about it, that these diseases could be cured. The third group, the leading citizens, needed to know a great deal more about it. In every locality there was a small group of people who were identified with and behind various progressive movements, the group that were interested in child welfare work, in the tuberculosis problem, in hospitals, clinics, etc. This class of people should be given a pretty full amount of fact. Those who were working in the State Department of Health and in the Federal service should be well informed so that in case the Federal subsidy for carrying on the campaign against venereal disease was discontinued there would be a body of people who would give a strong and intelligent backing to this work. It would be an advantage to have identified with the public health agencies a small group of intelligent laymen who could speak from that point of view. When it came to localities, the speaker said he suspected that the time was at hand when the different kinds of health workers must come together, so that there would not be one group for child welfare work, one for tuberculosis, etc., but that these different lines of welfare work should all be brought together and coordinated into one comprehensive health activity, something like the health centers. There should be one such comprehensive public health agency in each locality. There was one trouble among uninformed people, some of whom had said they would like to see the doctors fight it out among themselves as to who should pay for this work. The question of who was to pay should not stand in the way of getting people to the clinics. All the lay workers would like to see the physicians attached to health activities well paid, for they appreciated the work that was being done. All would like to see the private practitioner paid, but there was as yet no plan whereby the doctors in the clinics should receive due remuneration. This stood in the way of getting at this great mass of disease. The question of finances should not be allowed to stand in the way of bringing people where they

could receive curative treatment. In matters of legislation affecting public health the physician should be progressive and need not fear that the community would not support him. Experience had shown that the community was usually more ready to support public health legislation, and to spend money for the promotion of public health than we had been apt to think. So in the matter of the campaign against venereal disease the people would be found ready to follow those who led the way.

After the conclusion of the motion pictures a rising vote of thanks was tendered to Colonel Pierce and his associates for their very interesting and instructive presentation.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held January 27, 1920.

DR. LILLIAN K. P. FARRAR IN THE CHAIR.

THE program of the evening was arranged by the Obstetrical and Gynecological Staff of the Long Island College Hospital.

An Infected Hematocele Containing Bony Elements.—Dr. HARVEY B. MATTHEWS reported this case. He stated that the woman's chief complaint was pain in the lumbar-sacral region and backache. Her menstrual history had been normal until about a year before her present illness, when menstruation began to be irregular, every eighteen to twenty-one days, without pain. The patient had been curetted, after which she experienced some relief. She was admitted to the Jewish Hospital for post-abortion sepsis and pelvic cellulitis. During the first six days of her stay in the hospital her temperature ranged from 99° to 102.2° F. After the first six days her temperature ranged around 99° F. The uterus was the size of a four and one-half months pregnancy. She began to flow two weeks after leaving the hospital. Then for three weeks she did not spot. She then bled for two days, which she thought was a normal menstrual period. Her blood count at this time showed 13,000 white blood cells and 73 per cent. polynuclears. Her blood pressure was 123 systolic and 73 diastolic. Examination showed a median tumor extending across the abdomen toward the right side. There was a laceration of the pelvic floor and the cervix was pushed forward and upward. The uterus was only moderately tender. Pelvic abscess was diagnosed and drainage of the cul-de-sac decided upon. In draining the cul-de-sac bony elements appeared which were taken out piecemeal until it seemed that almost every bone in the body was removed. Following this procedure convalescence was excellent, and the patient was discharged 21 days after operation. Examination at this time showed a relaxed pelvic floor, the uterus anteflexed and a considerable amount of granulations along the line of the incision. The most interesting point in the case was the question when the fetus escaped into the abdominal cavity. Was it at the time the uterus was curetted, or was this an ectopic which had ruptured? Dr. Matthews cited several similar cases in the literature which had been traced to a puncture of the uterus which permitted the fetus to escape into the cul-de-sac. In two of these cases the abscess had made its own incision, rupturing into the uterus. In the final analysis it seemed to him that this was an ectopic that had gone to four months, become infected, and ruptured into the cul-de-sac.

Dr. HERMANN GRAD stated that he had had a case in which operation had revealed an infected ectopic with bone contents. In this case also the diagnosis was pelvic abscess. A history of ruptured ectopic gestation could be made out, about five months before patient came into the hospital for the abscess. After the rupture of the tube into the abdomen further development of the fetus must have gone on. The woman had continued to be in good health until finally infection occurred.

A Review of the Incidence of Forceps in 2000 Cases.—Dr. H. M. SHUTTER presented this study of 2,028 cases in the ward service of the Long Island College Hospital. He stated that among these 2,028 cases there were 60 forceps deliveries, or 2.88 per cent., one in every 34 cases. This, they believed, was a very low incidence; the first reason for this belief was that the cases were studied very carefully in the prenatal clinic; a second reason was because all the labors were conducted in bed; third, a tight abdominal binder was used, and, fourth, pituitrin was used in cases in which the fetal head was engaged, the cervix fully dilated, the fetal heart in good condition, and in which there was no obstruction in the outlet. Of the 60 cases 37, or 61 per cent., were low forceps; 18, or 30 per cent., were mid-forceps cases, and five, or 9 per cent., were high forceps operations. No one thing seemed to be accountable for the use of forceps. Of the forceps cases 81 per cent. were primiparæ, and 50 per cent. of these showed contracted pelves. The posterior position occurred in 48 per cent. of the cases as against 10 per cent. in the spontaneous cases. The number of women 25 years of age or over was 32, or 53 per cent. Dry labor occurred in 19, or 31 per cent. The indications for the use of forceps were delayed second stage in 65 per cent., maternal emergency in 10 per cent., and fetal asphyxia in 25 per cent. The maternal emergencies were lobar pneumonia, acute bronchitis, and cardiac decompensation. Every case was classified in the morbidity list if there was a temperature of 100.4° or over which lasted for forty-eight hours or longer. Of the high forceps cases 40 per cent. showed morbidity; of the mid-forceps cases, 22 per cent., and of the low forceps, 24 per cent. The total morbidity among the forceps cases was 25 per cent. The fetal results showed a brachial paralysis in one case, facial paralysis in two cases, and a stillbirth rate of 3.33 per cent. in the entire series. Of the forceps cases 18.33 per cent. lost their babies. Of the high forceps cases, 80 per cent. lost their babies; of the mid-forceps cases, 16.3 per cent., and of the low forceps, 10.8 per cent. Their experience warranted the conclusion that a high forceps operation was a dangerous procedure, seldom if ever indicated, and was not to be resorted to with impunity; in other words, that it had a definite danger both for the mother and for the fetus.

Surgical Intervention in Ascending Peritonitis of the Puerperal Type.—Dr. LEO S. SCHWARTZ made this presentation. He first showed a slide illustrating the result of conservative treatment of puerperal sepsis. These showed that the omentum had come down and the sigmoid had dropped down into the pelvis to wall off the infection and prevent it from spreading further. There was a class of cases in which early operative interference would help save life, that was, in those cases that developed an asthenic type of infection characterized by an ascending tenderness, pain, and an increase in the total white cell count, and polynuclears. Except for a sensitive cervix, the vaginal findings in these cases were negative. The severity of the symptoms was dependent upon the virulence of the organisms. In the presence of the colon bacillus or the gonococcus, the process was usually limited, but with the streptococcus or staphylococcus it was more serious, and might extend and involve the whole peritoneal cavity. It was during the early stage that surgery gave the best results by evacuating and drainage of the infected area.

Dr. SCHWARTZ then reported a case in which a curettage had been performed for the interruption of a two months' pregnancy. On the fourth day the patient's temperature rose to 104° F., and her pulse to 130. The abdomen became distended, and as palliative measures were ineffective a posterior vaginal incision was decided upon. A small quantity of purulent fluid was evacuated, and within four hours the temperature and pulse dropped and the patient was much relieved. Encouraged by the results in this instance, they decided to employ this procedure in other cases. Up to the present time they had employed it in eight cases, four post-abortion and four post-partum. They had found posterior vaginal section a simple procedure which could be performed easily and with the patient in bed. Dr. Schwartz gave a lantern slide of the technique of the procedure, which consisted in making a transverse incision of the vaginal mucous membrane and entering the peritoneal cavity; then with the fingers making gentle palpation, but not breaking up adhesions or looking for trouble. The incision was enlarged with two fingers to give exit to any accumulation of pus that might be found, and three strips of

rolled iodoform gauze folded to a width of about 1 inch were carried up into the cavity, one to each side and one to the center. These wicks of gauze were allowed to remain six or seven days and then removed. While the number of cases that they had treated in this way were too few to justify the drawing of conclusions, the results were so satisfactory that he felt justified in recommending use of posterior vaginal section as a simple, harmless, and effective procedure which reduced an already too high puerperal mortality.

Dr. HIRAM N. VINEBERG said that this subject had always interested him, and he was glad that the Brooklyn school was going to deviate a little from their ultra-conservative methods, but it was well to remember that one had to use judgment. However, the results which Dr. Schwartz had presented were very encouraging. The late Dr. Pryor had used this method, but did not limit it to pelvic peritonitis. One could not, of course, cure all cases by this method, and he would not advise everybody to make this incision with the patient in bed. It looked very pretty on the screen, but he had seen quite a number of cases, and one did not always find the dimple which had been indicated as the point at which the incision was to be made, and one did not always at once get into the peritoneal cavity. It required a great deal of gentleness in order to pass the gauze, and one could not do it well with the patient in bed. If he had any criticism to make it was that he would not describe the procedure as such a simple one, and he would not advise that it be done in bed. In fact, he had seen alarming hemorrhages occur as the result of injury to a branch of this uterine artery, with the scissors, dilating instrument, or fingers.

Dr. HENRY DAWSON FURNISS called attention to an article by Dr. Horsley in *Surgery, Gynecology, and Obstetrics*, in which he claimed that the benefits of drainage were not altogether due to mechanical effects because drainage was often placed where to be effective it would have to drain uphill, which was an impossibility, but that a biological factor was to be credited, namely, the insertion of a foreign body that caused irritation and produced a reversal of the lymphatic circulation. He thought that in the procedure just described the good results might be attributed to such a factor.

Dr. HERMANN GRAD said that another factor that might account in a measure for the good results Dr. Schwartz had obtained was the antiseptic action of the iodine. A gentleman from Brooklyn had asked him to try a certain preparation of iodine in septic cases, and he used this preparation in four puerperal cases. Whether or not the remarkable recovery that took place in the cases was due to the iodine injection he could not say, but in one case the improvement was so remarkable that it was really startling. The patient was septic, following a forceps delivery, and had a temperature of 106° F., and it did not seem that she could recover. In another case, in which a large abscess formed, a wonderful recovery followed the injection of the iodine. In olden times it was the practice to inject proteins in the body in order to cause a hyperleucocytosis in septic cases. While the drainage instituted might be responsible for the improvement there might also be other factors, and the benefit should not be attributed entirely to opening the cul-de-sac. The operation, as pointed out by Dr. Vineberg, was not very easy. It was quite possible to have a loop of intestine slip down into the incision, and he thought the operation should be done under the proper conditions.

Dr. FARRAR asked whether she understood correctly that the iodine was administered intravenously, and if so what was the strength of the solution used.

Dr. GRAD replied that he used a 3½ per cent. aqueous solution, giving it very slowly. It was advocated to be given intravenously, but in this case he had used 5 c.c. subcutaneously.

Dr. FARRAR said that Dr. Hunner spoke of opening not directly into the posterior vaginal fornix, but simply of making an incision posterior to the cervix, and following along with the finger until one got a suggestion as to where the abscess pointed, and in that way there was less danger of getting into the peritoneal cavity, one avoided meeting more immediately with the intestine, and was not invading new tissue.

Dr. VINEBERG asked Dr. Schwartz when he made this opening in the vagina, since just at the beginning of a peritonitis there was nothing walled off.

Dr. SCHWARTZ said that the question when to open the cul-de-sac was difficult to answer, unless one saw the patient. One could only judge by the tenderness and sensitiveness of the abdomen in the pelvic zone and the high leucocyte count. At this stage there was no mass in the pelvis. As to the danger of posterior vaginal section, he had done it in over 100 cases, and except for one case, a case of ectopic pregnancy in which there was hemorrhage, he had had no bad results and no hemorrhage.

The Value of Abdominal Exercise Pre- and Post-Partum.—Dr. HARRY KOSTER presented this paper, in which he said that considering the enormous amount of attention paid to the development of prophylactic measures in gynecology and obstetrics it was rather surprising that so little work had been done in the direction of improving the tone of the abdominal muscles, particularly so when it was universally conceded that the element of muscular activity, as a factor in the mechanism of labor and the maintenance of good health at all other times was a matter of utmost importance. Everyone was familiar with the flabby, flaccid pendulous abdominal wall which during parturition could not be counted on as an asset, and which during the nonparturient period was distinctly a liability, being a causative factor in the production of ptoses of the abdominal viscera. Where the muscle wall did not support the abdominal viscera palliative efforts had been exerted through the use of various anterior reinforcements, pads, and bandages, with considerable success. But such relief was not permanent. When the mechanical support was removed the symptoms recurred, because nothing had been done to strengthen the muscles which had lost their original elasticity after having been subjected to a period of increasingly forcible extension, exceeding the limit of physiological extensibility with perfect elastic recoil. In the normal state muscles extending from bone to bone were slightly stretched. This state of elastic tension insured a more prompt and effective contraction, as it had been shown experimentally that the amount of rise of a lever to which a muscle was attached, when excited by an electric stimulus of definite strength was greater when the muscle was placed under tension by adding a slight weight than if no weight were added. Muscle was extensile and perfectly elastic within limits. The extensibility of muscle for successive equal increments of weight gradually decreased, approaching zero as a limit. Before this limit was reached removal of the weights resulted in perfect elastic recoil. If the weight was increased beyond the zero limit, which was also the elasticity limit, the amount of extension then increased with increasing increments of weight up to the rupture point, and elastic recoil from beyond the elasticity limit was not perfect. Frequently an abdomen was seen, the wall of which was under tension only while the woman was in the upright position. When the woman was placed in the dorsal recumbent position the loose redundant wall spread over the flanks and pubes. It was evident that the tonus in these muscles was low and also that they had previously been stretched beyond their elastic recoil limit. A careful analysis of obstetric case records yielded as one of the conclusions the belief that many forcep deliveries might have been avoided by the application of a tight abdominal binder. The proper development of the muscles of the abdominal wall before pregnancy would obviate the use of the abdominal binder. Were the tone of these muscles sufficiently raised before pregnancy the wall would yield less readily and less completely to the gradually increasing pressure of the enlarging uterus, and there would be valuable aid in their synergistic rhythmic contractions during the uterine expulsive efforts. Were the tone of these muscles sufficiently raised before pregnancy a point in the improvement could be reached which would allow a margin of extensibility beyond that encountered in the parturient period without reaching the elastic recoil limit, and thus insure elastic recoil. Progressive muscular exercise could raise the quality of the muscle to a higher efficiency. Before maternity, therefore, the abdominal muscles should be prepared for the expected strain by raising

their power through progressive exercise. The essayist suggested an exercise which he said was ideal, inasmuch as it met with all the requirements regarding results, was capable of universal application because it could be practised at home without apparatus, and presented a wide range of gradation of effort necessary for its accomplishment, thus making it applicable to individuals having different strengths of abdominal walls. This exercise consisted in lying on the back, the entire lower extremity, from the hip down, acting as a single lever, was flexed on the abdomen to a line perpendicular to the resting surface, and then lowered. Throughout the exercise there should be no flexion at the knee joint. When the exercise was first begun the average woman would find it difficult to repeat the maneuver twenty-five times without pause, but it was astonishing to note the rapidity of increase possible and the concomitant improvement in muscular tone. An expenditure of not more than four minutes was necessary for the performance of the movement one hundred consecutive times, than which no greater daily number was needed to ultimately develop a firm, elastic supporting wall.

Dr. HAROLD BAILEY told of a visit to a sanatorium at Pompton, N. J., the Adams place, and of the work that was being done there in the muscular development of women, and that so far as he could tell from the picture shown on the slide Mr. Adams employed the same movements as Dr. Koster had described. He had the women lie on their sides and make the same movement back and forth, called the "scissors exercise." Mr. Adams weighed about 200 pounds, and in order to demonstrate what was being done stepped on the abdomen of one woman who had been undergoing training for six or eight months.

Dr. WILLIAM P. HEALY said that it had been his experience in recent years that the average young woman did not wear an abdominal support and did not wear corsets. He was a believer in advisability of wearing an abdominal support during pregnancy and preferred a corset that laced in the back and not in the front, and one that maintained a compact support. He had the impression that those patients who had strictly observed his instructions in this respect had had much simpler labors. He was under the impression that the presenting part came down into the pelvis much easier. Many of these women who were very slender and whose pelves were below the average in size were able to go about in public without feeling that they were attracting attention until two or three weeks of delivery, and they had had rather easy labors. These facts had prejudiced him in favor of the abdominal support. The question had been brought up as to whether the wearing of a firm support caused harm to the child. He had seen nothing that would lead him to believe that normal retention of the abdominal walls by a properly fitted support harmed a fetus floating in amniotic fluid. These exercises which Dr. Koster had described were very essential not only prenatally but also after the women had been delivered of their babies, and especially after over-distention had been caused by lack of support in the first pregnancy. He felt, however, that the exercises would not help a great deal if the muscles were not supported during pregnancy while the abdomen was enlarging.

Dr. WILLIAM S. STONE said he thought the practical application of this work was very valuable. He had had a little experience with it some years ago. It was one of Dr. Tucker's hobbies that women should exercise during the last weeks of pregnancy, and he told of wonderful success attained by this means. It was a great help in dilatation if the head was on the perineum when labor began.

Dr. FARRAR asked Dr. Stone what kind of exercises Dr. Tucker used.

Dr. STONE replied that one form was similar to those just described, and he also had the women bend over with the knees straight and touch the floor; that exercise not only developed the muscles of the abdomen but helped crowd the fetus into the pelvis.

Dr. KOSTER, in closing, said that with reference to the remark that the abdomen was not properly supported during the first pregnancy, that seemed to him confirmatory of the idea that the abdominal walls might better be strengthened before pregnancy. When the abdomen was supported nothing was being done to increase the tone of the muscles or to raise the possibility of extension with complete elastic recoil. It seemed to him better to advocate something that removed the cause of trouble rather than something that was merely palliative, though abdominal support during pregnancy was a valuable adjunct.

Cancer of the Uterus in Young Women.—Dr. GORDON GIBSON presented this paper, in which he asserted that malignant disease of the uterus in women under thirty was of sufficient rarity to warrant the report of six cases, one of which had come under the care of Dr. Polak, one of Dr. Beck, and four under the care of the writer. It had so long been taught that cancer of the uterus occurred about the time of the menopause that unless one was alive to the fact that it could occur at any age an early case in a young woman might be overlooked because "the condition present was not thought of." It was only by continued repetition of the teaching that any undue vaginal discharge, bloody or not, demanded investigation with the cancer mind, and that any cervix which bled easily on examination, or which showed any friability, should be considered as possibly malignant until proven not to be so by microscopical examination, that this process could be controlled. It was the writer's belief that in a case in which the diagnosis was clear clinically, one in which there was a definite growth of the cervix, it was better not to wait for a microscopical report, but to operate immediately, as it had been his experience recently to see the process destroy the cervix and invade the parametrium during the week elapsing between taking the specimen and receiving the report. Peterson, in a recent study of 500 cases of cancer of the uterus, found 23, or 4.8 per cent. of his cases under thirty years of age. Their percentage was still higher, being 6 in 61 cases studied, or 9.9 per cent. This percentage would probably decrease as the series was extended. The value of statistical study was open to question. It was not so important how often cancer of the uterus could occur under thirty as it was important that it did occur under that age. The result of any method of attack of this disease did not so much depend on the method as upon the condition as found. In other words, any operation, either abdominal or vaginal, which removed all the infiltration of malignantly growing cells would cure the patient, while any operation, either abdominal or vaginal, that did not remove all the diseased tissue was a failure in that particular case. It was true that in some hands more of the parametrium could be removed after isolation of the ureters by the abdominal route than by the vaginal method. After reporting in detail six illustrative cases, Dr. Gibson concluded as follows: (1) Cancer of the cervix occurred with sufficient frequency in young women to make it imperative that the condition be kept in mind. (2) Epithelioma was the type generally found in younger women. (3) The growth was much more rapid than in older individuals, and only when seen in the first three months could a radical operation be done. (4) The extension was especially rapid when the parametrium became involved and followed comparatively soon.

Dr. BAILEY said that he was glad to hear that the patient he had operated on and treated afterward was still alive. He agreed with Dr. Gibson in regard to malignancy in young women, and was rather surprised to see among such a small number of cases so many that were so young. His youngest case of malignancy was 23 years of age, but he had had a considerable number in the twenties. He agreed with Dr. Gibson as to the lack of necessity of waiting and that clinical diagnosis was sufficient to warrant one in proceeding to apply radium at once without waiting for the pathological report; then if the report came back negative no harm had been done, and if it came back positive the patient had the benefit of radium treatment before operation.

Dr. VINEBERG stated that it had been his experience to see two cases of carcinoma in young women within two months. One of these women had had syphilis and had been treated for syphilitic disease of the cervix, but there was no doubt as to the diagnosis of carcinoma. She also had a large mass in the parametrium, so that the case was inoperable, and he had referred the

patient to Dr. Bailey. The second case was one of those unfortunate ones for which the profession was not to blame. The patient had only noticed a discharge for a few months. She went to a physician who recognized the condition, and she had come to the speaker the next day. The cervix was simply eaten up by the carcinomatous mass and he felt that radium was contraindicated, because there was so much carcinomatous tissue that it would not be effective. He worked with the cautery for an hour, and succeeded in removing most of the carcinomatous tissue. She now had a retroperitoneal mass and the most they could hope was to relieve the distressing discharge. He was sure Dr. Stone and Dr. Bailey would agree that radium would not be of any value in that case at that stage. A further point that occurred to him was that while radium was destroying the cancer cells on the surface the cervix cancer cells had a chance to spread to the inner parts of the cervical tissue. He had recently seen an illustration of this in a case.

Dr. GIBSON, in closing, said that in regard to the radium there were two propositions to be considered. If the case was seen early one did not want to waste time trying radium, but should operate immediately and then put radium in directly following the operation. The question was whether that was the correct way or whether one should use radium first and then operate. In the late cases there was no question but that radium should be applied. The method they had been following was, instead of cauterization, to remove all the growth possible and then apply the radium immediately.

Advantages and Technique of Total Hysterectomy.—Dr. JOHN OSBORNE POLAK made this presentation, which consisted of a lantern slide demonstration of his technique of total hysterectomy. He propounded the question as to whether supracervical hysterectomy was the operation of choice in fibroid tumors of the uterus. This question, he said, should be definitely settled in the interest of the patient, for owing to the ease with which the average supracervical hysterectomy could be done the procedure had become routine with most gynecologists, even in the presence of those cervical conditions which should demand total ablation of the uterus. Hence the patient was frequently left with an infected, lacerated, or hyperplastic cervix which remained the seat of a focal infection. Such a cervix, with its chronic endocervicitis, not only kept up a persistent leucorrheal discharge, but owing to lymphatic extension the uterosacrals became and remained involved and caused persistent backache; thus a patient who had submitted to operation for the cure of her hemorrhage, leucorrhea, and backache, remained uncured of two symptoms of her chief complaint. Not only was this so, but she was in constant danger of the recurrence of cancer in the retained uterine stump. That this was a reality and not a fancy was proven by the fairly frequent occurrence of epithelioma in the conserved cervix. The advantages claimed for the supracervical operation were: (1) That it was more easily performed; (2) more rapid; (3) had a lower morbidity; (4) did not shorten the vaginal wall, and, finally, that by retaining the cervical stump the keystone of the arch remained, thus maintaining the conformity of the vaginal vault, and therefore prolapse of the vaginal walls was less likely to occur. Were these contentions borne out by the clinical experience of the trained gynecological surgeon? To this question Dr. Polak replied in the negative. In their clinic at the Long Island College Hospital, after a long experience with the supracervical operation, and after following the end results in several hundred cases, they had found that the retained cervix, except in non-infected nulliparæ, did cause trouble and that, unless the condition of the patient or the technical difficulties of the case were such that even a slight prolongation of the operation would increase the risk, total ablation should invariably be performed. Since adopting this plan they had come to consider that total hysterectomy was the safest and most certainly curative of all gynecological procedures, for not only had their patients been cured of their leucorrheas and backaches, but their morbidity and mortality had been lowered. Perfection of the technique which he demonstrated had made the complete removal of the uterus a relatively simple matter. The technique of total hysterectomy was as follows: After the patient had been catheterized and the vagina and cervix thoroughly iodinized, the patient was anesthetized in the Trendelenburg posture, which allowed the intestinal coil to gravitate into the upper part of the abdomen. The abdomen was then opened through a long abdominal incision to the right or left of the median line, extending from the pubis to the umbilicus, or even above it. Two fingers were then introduced into the long angle of the incision and the edges of the abdominal wound lifted up. This permitted air to enter the peritoneal sac, and further displaced the intestinal coils upward. The wound edges were then protected by towels and the tumor exposed by proper retraction. With a large pair of Jacob's forceps the tumor was drawn out through the abdominal wound and as completely eventrated as possible. After the tumor was completely mobilized it was drawn well over to one side to expose the infundibulo-pelvic and round ligaments. A clamp was then placed close to the uterus, including the tube, utero-ovarian ligament, and the upper part of the uterine artery, and the infundibulo-pelvic ligament was tied distal to the ovary. The round ligament was now picked up and tied and both were cut on the uterine side of the ligature. The same procedure was repeated on the opposite side. Traction was now made on the tumor, which allowed the broad ligament to recede so that its anterior and posterior layer might be easily separated and the uterine artery exposed. The anterior flap of peritoneum was now caught with a pair of mouse-tooth forceps, just anterior to the round ligament, and a pair of Mayo scissors passed beneath it across the front of the uterus. These separated the vesico-uterine fold from its uterine attachment, and when it was completely detached it was cut across from round ligament to round ligament. This permitted a complete separation of the bladder from its uterine and vaginal attachment, and also increased the mobilization of the uterus. The tumor was then pulled forward over the pubis, and the posterior fold of the peritoneum incised transversely, just above the point of attachment of the utero-sacral ligaments, and with the Mayo scissors was carefully separated from the posterior surface of the uterus. This freely exposed the uterine arteries and by traction on the tumor the ureters naturally slipped out of the way, and the uterine arteries could be grasped by a Kocher clamp with perfect safety, and the uterus cut free proximal to the clamp. If the arteries had been properly isolated and the clamp had been applied at a point just distal to the origin of the vaginal branch, the remainder of the operation was practically bloodless. The bladder was then retracted with a Doederlein retractor and the vagina exposed just below the cervical-vaginal junction. With a long pair of sharp pointed curved scissors the vagina was entered by a transverse incision, just below its attachment to the cervix. The air entered the vagina and at once ballooned it, and a pair of Jacob's forceps grasped the cut edge of the anterior vaginal wall, while a second pair of forceps grasped the anterior lip of the cervix. Upward traction was made on this and the cervix and vaginal wall again iodinized, and a strip of iodine-soaked gauze was passed from above downward through the vaginal wound. The incision of the vaginal wall was continued completely around the cervix at the cervico-vaginal junction. It might be necessary before cutting the uterus free to apply a Kocher clamp transversely, so as to include the posterior vaginal wall and each uterosacral ligament. This absolutely controlled all of the hemorrhage from the cut edge of the vagina, and allowed one to cut the uterus free from its posterior attachments. The tumor and uterus having been removed, a suture was placed through the anterior and posterior vaginal walls, whipping these two surfaces together. With the hemorrhage controlled and the vaginal vault closed, the round ligaments were brought into and sutured to the vaginal vault making relaxation of the anterior vaginal wall less liable to occur. Furthermore, care had been taken to preserve the utero-sacrals, and they also were attached to and sutured into the vaginal vault, thus maintaining its high position in the pelvis. The final step of the procedure was the peritonealization of all surfaces. This was done by uniting the pos-

terior fold of the broad ligament with the anterior, burying the stumps of the ovarian and uterine arteries, and carrying the bladder reflexion of the peritoneum over the vaginal stump. When the toilet was completed there was a smooth peritoneal face extending from one pelvic wall to the other.

Dr. VINEBERG agreed with Dr. Polak that it was a great advantage to remove the cervix and he did so in about 95 per cent. of the cases, but occasionally the condition was such that it was not wise to do so. He was a little disappointed, however, to hear Dr. Polak reverse his judgment as to the wisdom of conserving the ovary. He must also say that he preferred to leave the vagina open for the reason that one usually got better results and less likelihood of exudates from the complete operation than from leaving the cervix was because the vagina could be left open and if any secretions occurred they would drain away. There would be no prolapse and no cystocele unless it existed before the operation, and if there was a cystocele simply suturing the edges of the vagina together would not cure it. He did not think it was good surgery to bring down the round ligaments and attach them to the vaginal walls.

Dr. M. R. ROBINSON said the technique of abdominal panhysterectomy as demonstrated this evening by Dr. Polak corresponded in the main with the standard operation adopted in the leading hospitals of the country. This demonstration, however, served to further strengthen his conviction, arrived at long ago, that while there were some gynecologists who could do excellent general surgery, there were but very few general surgeons who were doing gynecological work as it should be done. He had very seldom seen a general surgeon do a complete hysterectomy. He usually preferred the supravaginal type, and chose for his operation the uncomplicated, freely moveable, large fibroids or myomas. The general surgeon as a rule paid very little attention to the condition of the pelvic relaxation, which was present in a large number of these cases, and which required just as much attention as the existing neoplasm in order to restore the patient to complete health. The speaker said he had often seen a badly lacerated infected cervix left behind after a supravaginal hysterectomy performed in twelve minutes by a general surgeon. How many general surgeons took the pains to suspend the remaining cervical stump to the round ligaments, as shown on the screen this evening, in order to prevent a future prolapse. He, therefore, maintained that the hospitals in which gynecology was not recognized as a special branch of surgery were not fulfilling their mission properly, and that careful special training only would yield the excellent results obtained by Dr. Polak.

Dr. POLAK, in closing the discussion, said he had evidently been misunderstood. His point was with reference to an anastomosis between the ovarian vein and the ovarian artery in conserving the tube with the ovary. If the tube was not conserved there was a "one ended circulation," and the ovary became swollen. The uterine artery was pushed off the broad ligament in order to maintain the circulation between the ovarian vein and the ovarian artery. This was carried on by vessels going from the ovarian artery to the tube and back to the ovarian vein so as to effect a complete anastomosis. Dr. Polak said he was not enthusiastic about conserving an ovary, because following hysterectomy an ovary did not continue to secrete for more than two years. Where an ovary alone was left after hysterectomy, adhesions, cicatrizations, and cystic degenerations were likely to occur.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

WEST VIRGINIA STATE BOARD OF HEALTH.

July 13, 1920.

ANATOMY.

1. Describe a transverse section of compact bone.
2. Which are the peculiar ribs that require special consideration.
3. Describe the shoulder joint, and name the ligaments.
4. Give a brief description of the fascia lata.
5. Give a brief anatomy of the great sciatic nerve, and what it supplies.
6. Give a brief anatomy of the small intestine, and name the divisions.
7. Name the principal salivary glands, and where located.
8. Give origin and insertion of the external oblique muscle.
9. Give the function, origin, distribution, and branches of the abducens nerve.
10. Give the origin, insertion, innervation, and function of the soleus muscle.
11. Give the development of nerve-tissue.
12. Give the development of the humerus bone.

PHYSIOLOGY AND HISTOLOGY.

1. What is characteristic in structure and function of the heart muscle?
2. Describe the spinal reflex arc.
3. Discuss the coagulation of the blood.
4. How are the systolic and diastolic blood pressures determined?
5. Describe gastric digestion.
6. Give the histological structure of the salivary glands.
7. Compare the inspired and expired air.
8. Describe absorption in the small intestine.
9. Give the histological structure of the kidney.
10. What are the islands of Langerhans; their function?
11. Discuss the nutritive value of protein food.
12. How is heat produced in the body?

CHEMISTRY AND MEDICAL JURISPRUDENCE.

1. Define molecular weight.
2. What is the most common element in nature?
3. Give the atomic weight and valence of hydrogen, lead, sulphur, and mercury.
4. How is H_2S prepared? Give formula.
5. Name five acids used in medicine and give their formulæ.
6. What is uric acid and tell all you know about it.
7. Describe the bismuth test for sugar in the urine; state objection to this test.
8. What effect have albumin and sugar upon the specific gravity of urine?
9. What chemical reaction takes place when hydrogen dioxide is applied to sloughing wounds?
10. Give the color, reaction, and specific gravity of normal urine?
11. Differentiate between idiocy and lunacy.
12. How do you determine that an incised wound was inflicted by a blunt or sharp instrument?

ANSWERS.

ANATOMY.

1. A cross-section of a bone shows *Haversian canals;* around these the bone is arranged in rings or *lamellæ;* between these are spaces (*lacunæ*) in which are bone *corpuscles.* Each canal is connected with the lacunæ which are concentric with it, and the lacunæ with one another by means of fine canals (*canaliculi*) into which project processes of the bone corpuscles. A Haversian canal with its lamellæ, lacunæ, bone corpuscles, and canaliculi form a *Haversian system.* In a section of bone several of these systems may be seen, the spaces between them being occupied by *interstitial lamellæ.* Lamellæ which are on the surface of the bone, parallel with its circumference, are *circumferential lamellæ.* A longitudinal section of bone shows the Haversian canals to be what their name indicates, channels running through the bone. Their communications with one another are also seen. In each canal are an artery and a vein. If a piece of bone is treated with dilute nitric acid, so as to dissolve the lime salts which it contains, or by some other method of *decalcification,* a small portion may be torn off, which upon examination shows the fibrous structure of the lamellæ. Such specimens also show the *perforating fibers of Sharpey,* which hold the lamellæ together; elastic fibers may also be observed.—(Raymond's *Physiology.*)

2. *The peculiar ribs,* are: The first, second, tenth, eleventh and twelfth.

3. The *shoulder joint* is an enarthroidal joint formed above by the glenoid cavity of the scapula and below by the head of the humerus. Its ligaments are glenoid, coraco-humeral, and capsular. The glenoid surrounds the edge, deepens the glenoid cavity, and is continuous above with the long head of the biceps tendon. The capsular ligament, extensive and loose, arises above it from circumference of glenoid cavity behind the ligament, is attached below to the anatomical neck of humerus, and is pierced by tendons of two or three muscles. The coraco-humeral, or accessory, is a fibrous band which extends obliquely downward and outward from the coracoid process to the anterior part of great tuberosity, strengthening the capsular ligament. A *synovial membrane* lines the joint, and forms the bursa under the subscapularis. It is reflected round the tendon of the biceps, and lines the bicipital groove. The *nerve supply* is from the circumflex and suprascapular nerves. The *arteries* are branches of the anterior and posterior circumflex, and the suprascapular.

4. *Fascia lata* of the thigh envelops the muscles and surrounds the limb. Above it is attached to the back of the sacrum and coccyx, to the iliac crest, to Poupart's ligament, pubic body and ramus, ischial tuberosity and ramus, and to the lower edge of the great sacro-sciatic ligament. The *ilio-tibial band* is a thickened part attached above to the iliac crest and below to the head of the fibula and outer tuberosity of the tibia. The fascia lata is attached below to the head of the tibia and sides of the patella, being strengthened by aponeuroses from the vasti muscles. Behind the fascia passes across between the hamstring muscles, enclosing the popliteal space.—(*Aids to Anatomy.*)

5. *The great sciatic nerve* arises from the sacral plexus, and passes out of the pelvis through the great sacrosciatic foramen, below the pyriformis muscle; it extends down the back of the thigh, passing between the great trochanter of the femur and the tuberosity of the ischium; at the lower third of the thigh it divides into the internal and external popliteal nerves. It supplies the hip-joint and the biceps, semitendinosus, semimembranosus, and adductor magnus *muscles.*

6. The *small intestine* is situated in the abdominal cavity. It begins at the pyloric end of the stomach, in the epigastric region and ends at the ileocecal valve in the lower part of the right lumbar region. Its average length is about 23 to 25 feet. It is divided into three portions, the duodenum, the jejunum, and the ileum. The duodenum is the first part of the small intestine, it is about ten inches long, and extends from the pylorus to the left side of the body of the second lumbar vertebra. The jejunum and ileum form the coils of the small intestine and are covered by the great omentum; they form the remainder of the small intestine, the upper two-fifths being the jejunum and the lower three-fifths the ileum; there is no line of demarcation between these two parts. The coils of the jejunum and ileum are suspended from the posterior abdominal wall by the mesentery. The wall of the small intestine is composed of four coats, a serous, muscular, submucous, and mucous.

7. The *salivary glands* are the two parotid, two sublingual, and two submaxillary glands. The *parotid gland* is the largest of the salivary glands, and is situated outside the mouth, below and in front of the ear; its duct is called Stenson's duct; it crosses the masseter muscle, pierces the buccinator, and opens in the mouth opposite the second upper molar tooth. The *submaxillary gland* is situated beneath the lower jaw, and its duct is Wharton's duct, which opens at the side of the frenum of the tongue. The *sublingual* gland is in the mucous membrane at the side of the frenum of the tongue, and its ducts (ducts of Rivinus) open on the floor of the mouth near the frenum of the tongue.

8. THE EXTERNAL OBLIQUE MUSCLE (OF THE ABDOMEN). *Origin:* From the external surface and lower borders of the lower eight ribs. *Insertion:* Into the anterior half of the outer lip of the crest of the ilium, into the linea alba, and (by Poupart's ligament) into the spine of the pubis.

9. THE SIXTH OR ABDUCENS OCULI. "*Origin.—Superficial:* From the sulcus between the pons and medulla, anterior to the anterior pyramid. *Deep:* floor of fourth ventricle beneath fasciculus teres. *Course.*—Pierces dura mater on basilar process and grooves side of dorsum ephipii to reach cavernous sinus; lies to outer side of internal carotid, and below the other nerves. Enters orbit by sphenoidal fissure, between the heads of the external rectus, lying above ophthalmic vein. *Distribution.*—External rectus (ocular surface.)" (*Aids to Anatomy.*)

It has *branches of communication* with the ophthalmic nerve and the carotid and cavernous plexuses. It is the motor nerve of the external rectus muscle of the eye.

10. SOLEUS MUSCLE. *Origin:* From back of head of fibula and upper third of posterior surface of fibula, from oblique line and internal border of tibia. *Insertion:* With the tendon of the gastrocnemius (making the tendo Achillis) into the lower part of the posterior surface of the os calcis. *Innervation:* Internal popliteal and posterior tibial nerves. *Function:* It extends the foot and ankle, it is used in standing, walking, dancing, etc.

11. *Development of nerve cells and fibres.* "All nerve-cells in the body are developed from the cells of the neural groove and neural crest of the early embryo; the neural groove closing to form the neural canal, the cells of which form the spinal cord and brain, and the neural crest giving off at intervals sprouts which become the rudiments of the ganglia. The cells which line the neural canal are at first all long columnar cells, but among these, and probably produced by cell division from some of these, rounded cells make their appearance, and presently from each neuroblast a process begins to grow out. This is the axon, and is characterized by its enlarged extremity. As it grows, it may emerge from the antero-lateral region of the canal and become the axis-cylinder of a motor nerve or anterior root-fibre. The dendrons of the cell appear somewhat later than the axon. The axis cylinder processes of some of the neuroblasts remain within the nerve-center, and are developed into commissural, association, or intra-central fibers. The sprouts from the neural crest contain the neuroblasts from which the posterior root-fibers are developed. Axons grow out from these neuroblasts in two directions, so that the cells become bipolar. One set, forming the posterior root-fibers, grow into the postero-lateral portion of the spinal cord and ramify in the developing gray matter; the other set, containing the afferent fibers of the spinal nerves, grow toward the developing anterior roots, and eventually mingle with them to form the mixed nerves. As development proceeds, the bipolar ganglion cells become gradually transformed in most vertebrates, by a shifting of the two axons, into unipolar cells. The ganglia on the sympathetic and on other peripheral nerves are developed from small masses of neuroblast cells which separate off from the rudiments of the spinal ganglia and give origin to axons and dendrons much in the same way as do the neuroblasts within the central nervous system.

The manner in which the medullary sheath and neurolemma of the nerve fibers are formed is not well understood. It is usually assumed that they are also epiblastic in origin and are developed from epiblast cells which grow out from the embryonic central nervous system along the axis-cylinder processes of the neuroblasts. But this is by no means clear. It is indeed possible that the medullary substance may be formed by the axis-cylinder itself and that the neurolemma with its nuclei may be derived from extrinsic cells, perhaps of mesoblastic origin. The neuroglia cells appear to be developed from epiblast cells of the wall of the neural canal, which, in place of giving off axon and dendrons like the neuroblasts, send out a number of fine processes in all directions from the cell to form the fibers of the neuroglia."—(Schäfer's *Essentials of Histology.*)

12. *Development of the humerus.*—"From *eight* centers, one for each of the following parts: The shaft, head, each tuberosity, the radial head, the trochlear portion of the articular surface, and each condyle. The nucleus for the shaft appears near the center of the bone in the eighth week, and soon extends toward the extremities. At birth the humerus is ossified nearly in its whole length, the extremities remaining cartilaginous. During the first year, sometimes even before birth, ossification commences in the head of the bone, and during the third year the center for the greater

tuberosity makes its appearance, that for the lesser being small and not appearing until the fifth year. By the sixth year the centers for the head and tuberosities have increased in size and become joined, so as to form a single large epiphysis. The lower end of the humerus is developed in the following manner: At the end of the second year ossification commences in the capitellum, and from this point extends inward, so as to form the chief part of the articular end of the bone, the center for the inner part of the trochlea not appearing until about the age of twelve. Ossification commences in the internal condyle about the fifth year, and in the external one not until about the thirteenth or fourteenth year. About the sixteenth or seventeenth year the outer condyle and both portions of the articulating surface (which have already joined) unite with the shaft; at the eighteenth year the inner condyle becomes joined; while the upper epiphysis, although the first formed, is not united until about the twentieth year."—(Gray's *Anatomy.*)

(Radasch's *Histology.*)

Function of cardiac muscle.—Cardiac muscle, like other muscle, is excitable and contractile; it responds to mechanical, electrical, chemical, and thermal stimuli. The principal differences between cardiac and ordinary voluntary, striated muscle are: (1) The strength of the response of cardiac muscle does not vary with the strength of the stimulus. The cardiac response is "all or nothing." The smallest stimulus is either incapable of causing a contraction, or, if the heart contracts, it is a maximum response. (2) Cardiac muscle possesses a long refractory period. (3) The heart is incapable of entering into a condition of tetanus. (4) Cardiac muscle has a long latent period. (5) Further, cardiac muscle has an inherent tendency to contract rhythmically quite apart from a nervous mechanism.—(From Lyle's *Manual of Physiology.*)

2. *Reflex actions* are involuntary or unconscious movements, due to suitable stimuli. They depend upon the integrity of the *reflex arc*, which is a complex made up of: (1) A surface capable of receiving an impression; (2) an afferent nerve; (3) a nerve cell capable of receiving and also of sending out impulses; (4) an efferent nerve, and (5) a surface capable of responding to the impulse conveyed by the efferent nerve.

Example: The patellar reflex consists of a contraction of the extensor muscles of the leg and a movement of the foot forward when the ligamentum patellæ is struck; the quadriceps extensor must first be slightly stretched by putting one knee over the other. Its integrity depends upon a healthy condition of the entire reflex arc, consisting of tendon, afferent or sensory nerve, posterior roots, and anterior horn of the spinal cord, the efferent or motor nerve, and the muscle itself.

3. When blood is withdrawn from the blood vessels of the living body it first becomes viscid, then sets, and is converted into a jelly-like mass. This is due to the formation of fibrin. The jelly contracts, forming the clot; and at the same time the serum is squeezed out from the clot. Various circumstances and conditions will hasten or delay the process of coagulation. In man, the blood generally becomes viscid in from two to three minutes; it forms the jelly-like mass in from five to six minutes; a few minutes later the serum begins to appear; and the whole process is completed in from twenty-four to thirty-six hours. The clot then floats in the serum. The process is thus summed up by Halliburton. From the platelets, and to a lesser degree from the leucocytes, a material is shed out called *thrombogen;* from the formed elements of the blood, but also from the tissues over which the escaping blood flows, is shed out an activating agent, called *thrombokinase.* In the presence of *calcium* salts, thrombokinase activates thrombogen in such a way that an active enzyme is produced, which is called *thrombin.* In the blood plasma a protein substance exists, called *fibrinogen.* Thrombin acts on fibrinogen in such a way that it is transformed into the insoluble stringy material which is called *fibrin,* this entangles the corpuscles and forms the clot.

4. "The individual whose blood pressure is about to be recorded should be placed in such a position that his heart, the artery the blood pressure of which is to be determined, and the manometer are at the same level. It is usual to record the pressure in the brachial artery. The india-rubber bag of the instrument should be wrapped around the bared arm, the metal covering of the bag should then be adjusted and firmly strapped in position. The india-rubber tube leading from the bag is then adjusted to the proximal limb of the U-shaped manometer which contains mercury. The experimenter places the index finger of his left hand over the radial pulse of the subject, and with his right hand he compresses the syringe and so drives air into the india-rubber tube and the india-rubber bag around the individual's arm. The pressure of the air in the bag around the arm is recorded by movement of the mercury from the proximal to the distal limb of the manometer. The operator keeps on pressing the syringe until oscillatory movements are seen at the surface of the mercury in the distal limb of the manometer; the mean point of maximum oscillations registers the diastolic pressure. If the pressure in the bag is still further increased, the oscillations diminish in amplitude and finally disappear, and at this point the pulse can no longer be felt at the wrist. The height of the mercury supported then registers the amount of systolic pressure. It will then be noted that the mercury has descended in the proximal limb of the manometer, and has ascended in the distal limb of the manometer: the difference between the two mercurial levels will be the blood pressure of the brachial artery. The normal systolic pressure in man is about 120 mm. Hg, and the diastolic pressure is about 100 mm. Hg. In women the pressures are about 10 per cent. less. In children the systolic pressure may be as low as 90 mm. Hg, with a diastolic pressure of about 80 mm. Hg."—(R. Hutchison.)—From Lyle's *Manual of Physiology.*

5. On *entering the stomach* the food is already crushed, mixed with saliva, and reduced to a pulp; it is rendered slightly alkaline, and a small amount of the starch has been converted into maltose; the proteids and fats are unaltered. *In the stomach,* where the contents are rendered acid, conversion of starch into sugar ceases, connective tissue of fats is dissolved, and fats are set free. Proteids are dissolved by the pepsin of the gastric juice and proteses and peptones are formed. The albuminous foods are dissolved for the most part, and a grumous mixture of peptones, liquid fats, and starches is formed, which is termed chyme, and is gradually passed through the pylorus into the intestine. The contents of the stomach at the close of gastric digestion are: Water, inorganic salts, acidified proteids, peptones, liquid fats, starch, cellulose, and the indigestible residues of various foods.

6. *Histological structure of the salivary glands.*—"The salivary glands are all compound tubular glands. In man the parotid is serous; the sublingual and submaxillary, mixed serous and mucous. Each gland consists of gland tissue proper and of a supporting connective-tissue framework. The framework consists of a connective-tissue *capsule* which encloses the gland, but blends externally with and attaches the gland to the surrounding structures. From the capsule *trabeculæ* pass into the gland, subdividing it into *lobes* and *lobules.* The gland tissue proper consists of systems of *excretory ducts* opening into *secretory tubules,* all being lined with one or more layers of epithelial cells. Each gland has one *main excretory duct.* This divides into branches—*interlobar ducts*—which run to the lobes in the connective tissue which separates them. The

interlobar ducts give rise to branches which, as they pass to the lobules in the interlobular connective tissue, are known as *interlobular ducts*. From the latter, branches enter the lobules—*intralobular ducts*—and *split up into terminal secreting tubules* which constitute the bulk of the lobule. As the smaller intralobular ducts are lined with cells of a secretory type, and probably take part in the elaboration of the secretion of the gland, they have been called *salivary* or *secreting* tubules. These, in the submaxillary and parotid glands, open into tubules which have a narrow lumen and are lined with low or flat epithelium; lying between the secreting tubules and the terminal tubules, they are known as *intercalated or intermediate tubules*. From the interlobular connective tissue delicate extensions pass into the lobules, separating the gland tubules. The glandular tissue is known as the *parenchyma* of the gland in contradistinction to the connective or *interstitial tissue*."—(Bailey's *Text-Book of Histology*.)

7.

	EXPIRED AIR.	INSPIRED AIR
Oxygen	16.6 per cent.	21 per cent.
Nitrogen	79 per cent.	79 per cent.
Carbon dioxide..	4.4 per cent.	0.04 per cent.
Other gases.....	Often present.	Rare.
Watery vapor...	Saturated.	Variable.
Temperature	That of body.	Variable.
Volume	Diminished.	Varies.
Bacteria	None.	Always present.
Dust	None.	Always present.

8. *Absorption of carbohydrates.*—"During digestion the greater part of the carbohydrate of the food is converted into the glucoses. These are comparatively small molecules which are readily dissolved and easily passed through the columnar cells into the portal vein radical which lies beneath. It is possible that some maltose may be absorbed by the columnar cells, and that during its passage through these cells it is converted into dextrose before it enters the portal vein radicals. It is possible that in these columnar epithelial cells the glucose, which is being absorbed, is linked to the cell protein, and that, further down the cells, this loosely combined substance is split into two, the dextrose passing into the portal vein radical and the protein molecule remaining intact in the columnar cells and ready to combine with fresh glucoses to be passed through the cells. A small proportion of the dextrose, which is carried to the liver, goes on unchanged to the tissues to be assimilated, but the greater portion of the absorbed glucose on arriving at the liver is stored there by the liver cells as glycogen."

Absorption of fat.—"Fat is not absorbed as fat, but as glycerin and fatty acid or soap. It is generally accepted that the fatty acid set free in the intestine is dissolved by the bile salts, and in this way, together with the glycerin, is absorbed by the columnar cells, but that during absorption a lipase which is contained in the columnar cells re-synthesizes, by reverse action, the glycerin and fatty acid. In this way minute fat particles are found near the bases of the columnar cells, and these may be demonstrated by staining with a 1 per cent. solution of osmic acid. The fat globules are further taken up from the columnar cells by some of the lymphocytes, which are capable of exhibiting ameboid movements, and which are found in the lymphoid tissue between the columnar cells and the central lacteal. The fat is then deposited in the central lacteal by these ameboid cells, and in this way it gets into the general lacteal stream, and thence into the thoracic duct. The bile salts, which have been absorbed by the columnar cells, in all probability get into the portal vein radical, and in this way are taken back to the liver to be excreted again in the bile. After a fatty meal minute globules of fat may be demonstrated in the blood plasma of an animal; but they disappear rapidly, possibly existing in a soluble and invisible form absorbed to the blood proteins before they are deposited in the fat depots of the body."

Absorption of proteins.—"The view previously held with regard to the absorption of protein was that during digestion protein was finally converted into peptone, and the peptone so produced was absorbed by the columnar cells over the villi, and built up again by these cells into serum albumin and serum globulin, the chief proteins of the blood plasma. The view generally accepted now is that protein is completely hydrolyzed into the cleavage products known as amino-acids in the intestine; and it is these amino-acids which, being smaller molecules than the original protein, readily pass through the striated free border of the columnar cells over the villi and so get into the protoplasm of these cells. Here a synthesis takes place, and some simple and aromatic amino-acids are converted by the columnar cells into serum albumin and serum globulin, the native proteins, and this protein is conveyed to the tissues."—(Lyle's *Manual of Physiology*.)

9. "The kidney is a compound, tubular gland composed of microscopic tubules whose function it is to secrete from the blood those waste products which collectively constitute the urine. If the apex of each pyramid be examined with a lens, it will present a number of small orifices, which are the beginning of the uriniferous tubules. From this point the tubules pass outward in a straight but somewhat divergent manner toward the cortex, giving off at acute angles a number of branches. From the apex to the base of the pyramids they are known as the tubules of Bellini. In the cortical portion of the kidney each tubule becomes enlarged and twisted, and after pursuing an extremelv convoluted course, turns backward into the medullary portion for some distance, forming the descending limb of Henle's loop; it then turns upon itself, forming the ascending limb of the loop, reenters the cortex, again expands, and finally terminates in a spheric enlargement known as *Müller's* or *Bowman's capsule*. Within this capsule is contained a small tuft of blood vessels, constituting the *glomerulus*, or *Malpighian corpuscle*. Each tubule consists of a basement membrane lined by epithelium cells throughout its entire extent. The tubule and its contained epithelium vary in shape and size in different parts of its course. The termination of the convoluted tube consists of a little sac or capsule, which is ovoid in shape and measures about 1/200 of an inch. This capsule is lined by a layer of flattened epithelial cells, which is also reflected over the surface of the glomerulus. During the periods of secretory activity the blood vessels of the glomerulus become filled with blood, so that the cavity of the sac is almost obliterated; after secretory activity the blood vessels contract and the sac cavity becomes enlarged. In that portion of the tubule lying between the capsule and Henle's loop the epithelial cells are cuboid in shape; in Henle's loop they are flattened, while in the remainder of the tubule they are cuboid and columnar."—(Brubaker's *Physiology*.)

10. *The islands of Langerhans* are small clumps of cells scattered through the pancreas and which are not connected with the rest of the pancreas physiologically. They are supposed to produce an internal secretion which in some way (not at present determined) influences carbohydrate metabolism.

11. *The nutritive value of protein food.*—"Formerly it was believed that all the different proteins (with the exception perhaps of gelatin) have an equal nutritive value. But the knowledge that the composition of these proteins varies in regard to the number and character of their constituent amino bodies, and the fact that each animal out of the complex offered to it in its food selects certain amino-acids in certain proportions from which to reconstruct its own peculiar body proteins, suggest naturally the thought that the different proteins may have different values in nutrition. Experiments have demonstrated, in fact, that this is the case. From the standpoint of supplying the energy needs of the body, the proteins are, so far as we know, pretty much of the same value, but from the standpoint of supplying material for tissue construction they may differ a great deal. Some proteins, when fed together with an adequate supply of non-protein material and water and salts, furnish all the nitrogenous compounds necessary for maintenance and growth; others under the same conditions fail to support growth or maintenance, or both. The former group may be spoken of as *complete* or *adequate* proteins, the latter as *incomplete* or *inadequate* proteins. The difference between the two kinds seems to lie in the character of the amino-acids of which they are composed. Some of the amino-acids which the body tissues need for repair or growth may be made in the body from other amino-acids,

glycin, for example, but others apparently must be furnished in the protein of the food, and if they are lacking, tissue construction is not possible."—(Howell's *Text-Book of Physiology.*)

12. *Heat is produced in the body by:* Oxidation; muscular action; the action of the glands, chiefly of the liver; the food and drink ingested; the brain; the heart; and the thermogenetic centers in the brain, pons, medulla, and spinal cord.

"The immediate source of the body heat is to be found in the chemical changes which take place in all the tissues and organs of the body. Each contraction of a muscle, each act of secretion, each exhibition of nerve force, is accompanied by the evolution of heat. The chemical changes are for the most part of the nature of oxidations, the union of oxygen with the elements, carbon and hydrogen, of the food principles either before or after they have become constituents of the tissues. The ultimate source of the body heat is the latent or potential energy in the food principles, which was absorbed from the sun's energy and stored up during the growth of the vegetable world. In the metabolism of the animal body the food principles are again reduced through oxidation, directly or indirectly, to relatively simple bodies, such as urea, carbon dioxide, and water, with a liberation of a large portion of their contained energy which manifests itself as heat and mechanical motion."—(Brubaker's *Physiology.*)

CHEMISTRY AND MEDICAL JURISPRUDENCE.

1. *Molecular weight* of a substance is the weight of a molecule of the substance as compared with the weight of an atom of hydrogen; it is, also, the sum of the atomic weights.

2. The most common element in nature is oxygen.

3.

	ATOMIC WEIGHT	VALENCE.
Hydrogen	1	1
Lead	207	2 or 4
Sulphur	32	2 or 6
Mercury	200	1 or 2

4. H_2S *is prepared* by the action of dilute sulphuric acid on ferrous sulphide:

$$FeS + H_2SO_4 = FeSO_4 + H_2S.$$

5. *Five acids used in medicine.*—(1) Acetic acid, $CH_3.COOH$; (2) Boric acid, H_3BO_3; (3) Hydrochloric acid, HCl; (4) Phosphoric acid, H_3PO_4; (5) Sulphuric acid, H_2SO_4.

6. *Uric acid* is a crystalline solid, colorless, odorless, and tasteless, almost insoluble in water; it is a weak, dibasic acid, with the formula $C_5H_4N_4O_3$. It is found in small quantities in human urine, chiefly as the disodic salt. On being heated uric acid is decomposed into urea, ammonium carbonate, hydrocyanic acid, and cyanuric acid. It is closely related to the purine bases and may be derived from the purines of the food and of the tissues. It gives the murexide test.

7. *Bismuth test for sugar.*—"Equal portions of the liquid are placed in two test tubes, to each of which enough solution of Na_2CO_3 is added to make the reaction distinctly alkaline, and to one a little powdered bismuth subnitrate, and to the other a little powdered litharge are added. The contents of the two tubes are then heated to boiling, when, if the bismuth powder becomes black and the litharge remains unchanged, the presence of a reducing sugar may be inferred. The purpose of the litharge is to guard against error from the presence of sulphur compounds, which blacken both the bismuth and lead powders."—(Witthaus' *Text-Book of Chemistry.*)

Objections to the test.—It cannot be used in the presence of albumen; sulphur compounds vitiate the test.

8. The presence of *albumin* in the urine makes the specific gravity less; the presence of *sugar* in the urine makes the specific gravity greater.

9. When *hydrogen dioxide* is applied to sloughing wounds there may be effervescence, in consequence of the liberation of oxygen.

10. *Normal urine* is of a yellowish color, acid reaction, and has a specific gravity of about 1015 to 1025.

11. *Idiocy* differs from other states of insanity in the fact that it is marked by a congenital defficiency of the mental faculties. There is not here a perversion or a loss of what has once been acquired, but a state in which, from defective structure of the brain, the individual has never been able to acquire any degree of intellectual power to fit him for his social position. It commences with life and continues through it."—(Taylor's *Medical Jurisprudence.*)

12. A wound inflicted by a blunt instrument will have somewhat of the appearance of a contused wound; the edges will not be so clean cut as in the case of a wound inflicted by a sharp instrument, and moreover, the surrounding tissues will also be more or less bruised.

(To be continued.)

BULLETIN OF APPROACHING EXAMINATIONS.

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†
Alabama*	S. W. Welch, Montgomery	Montgomery...Jan. 11

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular state.

The Ovary as a Cause of Pain.—Aleck. W. Bourne, in summing up a discussion on this subject, suggests the following: (1) That the ovary is a much less common cause of pain than usually believed. (2) That it does cause pain in some cases of premenstrual congestion and "middle-pain," in all cases of varicocele salpingo-oöphoritis and ovarian prolapse, with or without displacement beneath the fundus of the retroverted uterus. (3) That the key to the diagnosis is the presence of physical signs of ovarian fixity or displacement or excessive tenderness, discovered by the bimanual examination. (4) That varicocele may exist without discoverable physical signs, but is usually associated with ovarian prolapse and retroversion of the uterus. (5) That the commonest errors of diagnosis are made in cases of neurasthenia.—*The Clinical Journal.*

PREVENTION OF RESPIRATORY DISEASES.*

BY CHARLES LYNCH, COLONEL, M.C., U.S.A.,

WASHINGTON, D. C.

IN the midst of the present world turmoil which has followed the great war and not less from the experiences of the war itself, it is difficult to realize that war is other than a wholly destructive process. Fortunately for mankind this is not the case, however. Without naming other possible benefits from war, I will curtail my discussion at once by limiting it to the prevention of disease due to war experience. Much of permanent value in preventing illness and untimely deaths has resulted from such experience. Doubtless if other than an American were telling this story, he would find good illustrations of what I have said in the war history of his own nation, but the point can be proved so very easily from our own war history that it is not necessary to go outside of it.

The Spanish-American War was the first war fought by us under modern conditions so far as medical science is concerned. I am sure that many in this audience will recollect the medical triumphs of that war. Yellow fever has been almost eliminated as a result. Its old hot beds—Cuba and Panama—no longer have cause to fear it. Their bondage is broken. The Panama Canal has been built and this was made possible primarily through the knowledge of how to prevent yellow fever gained by Major Walter Reed and the Medical Department of our Army in Cuba. The name Gorgas stands out among the sanitarians of all time.

Over 20,000 cases of typhoid occurred among our troops at home in the summer of 1898. The epoch-making work of Reed, Vaughan, and Shakespeare followed with the establishment of the fact that contact infection is of far more importance under conditions of camp life than is contaminated water supply which had been regarded as mainly responsible before that date. Their investigation proved of great value in preventing typhoid before Colonel Russell developed for us so successful a system of vaccination. The Spanish-American War opened up a new domain, the Tropics, which at that time had not been so well studied from the medical standpoint as the other parts of the world. In Porto Rico, Colonel Ashford discovered the presence of hookworm in 1900, while later he succeeded in reducing the high mortality from it by about 90 per cent. He treated some 300,000 patients in 1903-4. He is now at work on tropical sprue in the same field. In the Philippines, Colonel Craig did some notable work on malaria and dysentery; also on certain parasite amebæ, and in other important directions. There, too, Colonel Vedder made important investigations on beriberi in connection with its dietetic origin. This officer also was the first to determine that emetine has a specific action in amebic dysentery. Colonel Whitmore established the Pasteur Institute in Manila, investigating rabies and tropical dysentery. Colonel Chamberlain also did important pioneer work as head of the tropical disease board in the Philippines. In Cuba, General Kean did yeoman service in the prevention of infectious diseases.

The sum total gained by these efforts to save human life cannot be measured in figures. Their effects were too world-wide for that. Without any question, in much less than 25 years they have amounted to tens of thousands. I am sure my first point that wars sometimes contribute in large measure to the saving of life through knowledge gained of the prevention of disease has been proved without going any further. But it may be interesting to know that so good an authority as General Leonard Wood once said that the whole cost of the Spanish-American War had been more than repaid by the information gained which led to the control of yellow fever alone.

The medical profession entered the World War, I think, with high hopes. We had a magnificent sanitary record to point to on the military side, our accomplishments in civil sanitation had been no less notable, and the best trained sanitarians, both civilian and military, were available to our forces. Nor were we lacking in knowledge of where our danger lay so far as disease was concerned. Our experiences on the Mexican border in 1916 indicated that respiratory diseases would be the class of disease most to be feared in a war of to-day. In fact, this prophecy was freely made before we became actively engaged.

The figures taken from the last annual report of the Surgeon General show that our hopes have been justified, except that we have made no appreciable advance as yet in the control of the respiratory diseases. An enormous reduction in deaths occurred, but this was due to a better knowledge of intestinal and insect-borne diseases, as well as smallpox, etc. But let the figures speak for themselves.

"The number of deaths from pneumonia is slightly greater than for the Civil War comparison and much greater than for the Spanish War comparison. The Spanish War rates were low because the war period

*Read before the Alumni Association of the College of Medicine of Syracuse University at the annual meeting held June 12, 1920; published with permission of the Surgeon General, U. S. Army, who is not responsible for any opinion expressed or conclusions reached herein.

was entirely in warm weather when pneumonia is infrequent. The greatest cause of the high pneumonia rate for the present war was the epidemic of influenza, a factor which occurs only about once in thirty years. Had this epidemic not occurred the rate would have been much lower than for the Civil War and probably lower than for the Spanish War. *Taken all in all, however, it must be confessed that the secret of the control of respiratory diseases, particularly pneumonia, still remains undiscovered."*

	Number of deaths occurred in present war, Sept. 1, 1917—May 2, '19. Average strength approximately 2,121,396.	Number of deaths that would have occurred if the Civil War death rate had obtained.	Number of deaths that would have occurred if the Spanish-American War death rate had obtained.
Typhoid fever	213	51,133	68,164
Malaria	13	13,951*c*	11,317
Dysentery	42	63,898*b*	6,382*b*
Smallpox	5	9,536	37
Pneumonia	41,747*a*	38,962*a*	6,086*a*
Scarlet fever	167	112	222
Diphtheria	100	1,188	149
Tuberculosis	1,220	9,574	631
Meningitis	2,137	3,859	4,081
Other diseases	3,768	34 881	15,587
Total for disease	49,412	227,094	112,656

a. Includes deaths listed from measles, influenza, empyema, inflammation of the lungs and pleurisy, as well as pneumonia.
b. Includes dysentery and diarrhea.
c. Includes malaria and remittent and congestive fevers.

It will perhaps now be useful first to consider the theory, or theories, of transmission of the respiratory diseases which obtained in largest measure at the beginning of the World War and during its course. They are embraced under the term "droplet infection." Of course everybody knows what droplet infection is, or thinks he does. Minute drops are expelled in the act of coughing or loud speaking. They contain the infective agent. The recipient inhales them from the air and thus becomes infected.

Based on this theory, procedures were early put into operation in the army which, theoretically at least, would diminish the dangers of such transfers from man to man. That they likewise diminished other possible methods of transmission is true and unfortunate from the scientific point of view, as this much increased the difficulties in many cases in reaching correct conclusions as to the exact method of transmission.

The most important of these procedures were wider separation of men in tents and barracks and separation first of all to give maximum distance between the mouths and noses of the men. The head and foot sleeping of adjoining men is an example of this, as is also seating soldiers on only one side of the table at mess. Cubicles were used, largely in hospitals, to impose an aerial barrier between men in adjoining beds. Free ventilation was also advocated in the belief that this produced dilution of germs floating in the air. Floors were oiled so that the infected material falling to the floor would be caught in its sticky covering and would not be kicked up to infect other men. Then masks were used, at first in hospitals only, then en route to hospital and finally, during the influenza epidemic especially, quite generally throughout some camps.

Intentionally nothing has yet been said on quarantine and vaccination. These procedures are of course based on other theories. Quarantine excludes all contagious individuals from the well. In theory at least it can be made effective, and sometimes is under army conditions. Rarely is much accomplished by it, however. There are too many loopholes and closing them effectually would tie an army hand and foot. Vaccination for pneumonia has up to the present time no figures to commend it. Neither quarantine nor vaccination will be referred to again.

There is, of course, no disposition on my part to criticise what has been done. It had a scientific basis theoretically and droplet infection had then, and has still, I think, the general support of the medical profession.

The results have already been given. If figures do not lie, they are to say the least very disappointing. There are other figures for comparison, but these are perhaps even more disappointing. I am speaking of the relative death rates for pneumonia between army and civil population of the same age period. They are fragmentary even for the period of the influenza epidemic, yet in order to secure anything authoritative, it is essential to confine ourselves to that period. The best we have been able to secure came to us in a private communication from one of our largest insurance companies. Better opportunities for securing accurate statistics exist in the army than in civil life, it is true, but this does not help greatly here, as we are searching for a comparison with our civil figures. The army death rate from respiratory diseases during the influenza epidemic was just about twice that of the policyholders of the insurance company in the same age group—20 to 34; 14 per thousand in the army as compared with 7 per thousand in civil life, as represented by the policyholders in question. If the civilian life figures can be taken as a fair measure for civilians, and I am quite sure that we shall be led into no material error by so accepting them, our only conclusion can be that, with all that was done in a sanitary way in the army as compared with civil life during the influenza epidemic, pneumonia deaths were not only not less in the army, but actually double those in civil life. From all that has been said, it is certainly fair to conclude that at the time of the influenza epidemic we had not found the answer to the control of respiratory diseases.

To a few sanitarians the droplet theory of infection in respiratory diseases never much appealed. Speaking only for myself, adequate proof was lacking to my mind. Dose is a big factor in infection and despite some laboratory experiments in projecting non-pathogens to some distance from the mouth, it seemed to me that, save under very exceptional circumstances, we must assume, if we accept the theory of droplet infection, that these droplets are not subject to the laws of gravitation and that the recipient swims through a sea created by them much as a fish swims through water. Likewise, he would have to have gill slits like the fish. So far as I know, no one as yet has collected any figures which offer any proof that these various measures of preventing droplet infection are of value, though it is fair to say that many good men say that in their opinion they served to lessen the spread of respiratory disease. A British commission on meningitis reduced the percentage of car-

riers by spreading men out more widely in barracks, but at the same time they removed the carriers then present. I mention this because it is sometimes stated as a proof of the benefits of wider separation of men in barracks. Of course it is no proof at all.

Mere chance attracted my attention, and that of my associates, to other possible avenues of transmission. I should say right here that some of these associates, notably Lieutenant-Colonel Cumming, have carried on experiments in indirect transmission much further than I have. Our first observation regarding insanitary methods of washing mess kits were made as early as August, 1917, at Tanforan, a small camp on the old race track near San Francisco, then occupied by the 144th Field Artillery in process of organization. We found the accepted method of washing mess kits was by setting out two or three pails of lukewarm water, into which each man plunged his mess gear and hands, after scraping the former into another pail. Later this organization had a severe and fatal epidemic of measles, the deaths being due to the ensuing pneumonia.

Now to explain in some detail what our conclusions were from this Tanforan experience. Of course we concluded at once that the practice of more than 200 men plunging their mess gear—mess tin, knife, fork, spoon—and hands, into the same dirty water was a most disgusting one. Later on, however, it came to us that not only was this disgusting but that it might have great sanitary importance; that is to say, we wondered if in straining at the gnat we had not been swallowing the camel, the gnat in this case being represented of course by the direct method of transmission by droplets, and the camel by the indirect method, the saliva of infected men being carried to their hands and eating utensils, then to the mess kit washing water, thence to other men's kits and hands, and finally to the mouths and hands of the recipients. This possibility occurred to us nearly three years ago. But no opportunity to study the question presented itself for some time. We have written a good deal in recent medical literature regarding indirect transmission of respiratory diseases or, as we prefer to call them "saliva-borne diseases," our point here being that this is the active agent in transference and to use the word "respiratory" gives a false idea as the inference is drawn that transfer is direct from respiratory apparatus to respiratory apparatus in the act of respiration. We have made no attempt as yet to summarize all our evidence, as it should be, or even to indicate what we consider most convincing. I will try to do so this afternoon as well as the necessarily limited time permits.

Our evidence is of two classes—(1) Field; (2) Laboratory. Field will be discussed first. When the influenza epidemic struck us at Newport News we had two groups of soldiers, one of which used mess kits which were washed in tepid water; the other group used table ware or washed their mess kits in boiling water. Our consolidated tabulation shows the latter—the table ware group—including the individual method but with boiling water, had a strength of 9,778 with 412 cases of influenza, and the former—the individual mess kits in tepid water—had a strength of 12,727, with 2,543 cases. Our method of investigation was simply to take these groups as we found them and to set down the results. Fourteen different organizations were concerned, and so far as we could make out, there were no differences in their living conditions except their mess sanitation. Their susceptibility to influenza seemed to be quite the same so far as their history went. While time does not permit going into these various organizations in detail, I desire to invite particular attention to one of our posts. This was Pig Point, Virginia, an Ordnance depot, where high explosives were stored, and consequently wholly and widely separated from other military and civil communities. Besides the soldiers present, many civilians were employed there. They, and the small Ordnance organization, constituted 1,150 persons, and messed from table ware. Their rate of influenza for the 18-day period was 82 per thousand, with an average daily incidence of 4.5 per thousand. The two Fire and Guard organizations, whose strength was 445, ate from mess kits washed by the old line method. In 18 days they had 171 cases. In every respect the two Fire and Guard organizations were better off from the sanitary standpoint than the greatly overcrowded civilian group, save only in their method of washing their eating utensils.

Our rates at Newport News for the whole epidemic of influenza compared very favorably with other camps. Furthermore, our death rate was less than the figures given for the average civilian population. A word of explanation as to the reasons for this is needed here. We were fortunate in having a number of organizations eating from table ware, also others that were boiling their mess kits prior to the epidemic. Then as soon as we concluded that the usual method of washing mess kits was dangerous, we changed it to boiling them, and this for all the organizations in the Port. Our conclusions from our first study were as follows:

1. Influenza, as well as the other so-called airborne or respiratory diseases, is essentially a hand-to-mouth infection.

2. There are major and minor modes of transmission by indirect contact—by the former through tepid mess-kit washwater, and by the latter through intermediate inanimate objects, the hand being the conveyor in both instances. Among troops approximately 75 per cent. of the cases arise by the major route. This applies to troop transports as well as camps.

3. Transmission by direct contact is only subsidiary to the indirect routes.

4. The adoption of a universal method of washing mess kits in boiling water will enormously reduce the prevalence of all mouth-borne infections.

5. The prevention of the hand-to-mouth infections may be accomplished by any measure which will prevent the unclean hand from visiting the mouth and nose and by the thorough cleansing of the hand after all such visits.

6. The incubation period of influenza would appear to be from two to three days.

7. An epidemic of influenza among troops may be controlled by elimination of hand-contaminated dish water.

A little later we were able to supplement somewhat the figures obtained in the influenza epidemic at Newport News, giving us a total of 66,076 troops.

In one group of collective table-ware washing there were 33,452 men, among whom 1,710 cases of influenza occurred, giving a daily incidence rate per thousand of 3.7, and a period rate per thousand of 51.1. The individual mess-kit washers were represented by 32,624 men and had 8,208 cases of influenza, a daily incidence rate per thousand of 18 and a period incidence rate per thousand of 252. It will be noted that there were five times more cases in the latter group. In order to ascertain if the same condition obtained in the civil population during the influenza epidemic, we examined certain restaurants in which washing machines and boiling water were used, as well as those in which the dishes were hand washed. In six first-class restaurants, washing machines and water at or near the boiling point, of 1,350 employees, 13 had influenza, or a rate of 9 per thousand. In six eating houses in a poor district, dishes hand-washed, of 25 employees, 7 had influenza, or 40 per thousand. In four department stores in the shopping district, of 13,500 employees, 181 had influenza, a rate of 13 per thousand. These stores employed washing machines and boiling water. In an employees' dining room in another department store in the shopping district, of 3,100 employees, 250 had influenza, a rate of 84 per thousand. Their dishes were hand washed. This again confirms the efficacy of the pasteurization of eating utensils.

Investigation on the same general lines was made by Colonel Cumming of influenza-pneumonia as influenced by dish washing in 370 public institutions. This was done by means of a questionnaire. The institutional population on which the report is based was 252,186. There were 84,748 inmates in institutions in which machine washing was employed for dishes. Their mortality per thousand population was 10.4. In the 167,438 in institutions in which hand washing was employed for dishes, the mortality per thousand was 22.9—a rate twice as great.

The laboratory work carried on was exhaustive. I can only indicate the more important findings here.

As a matter of fact, before any of our field work was done and as early as the winter of 1917-1918 in San Antonio, we made examinations of different classes of soldiers to ascertain the streptococcus index. This work was attempted because it seemed to us there must be something to account for the high pneumonia rate in soldiers. In recruits we found streptococcus in 5 per cent. I might mention that another observer, in 32 rural recruits recently found no streptococci at all, thus in a measure confirming our observation; but as I have said in recruits as they ran at San Antonio, the rate was 5 per cent., and from month to month this increased with length of service. According to our findings, which were based on approximately 6,000 examinations, this is a camp and not a hospital infection. This caused grave doubt of the usefulness of cubicles and masks in hospital. In our opinion this is closing the door after the horse has been stolen. Of those who entered the hospital with measles, 36 per cent. were streptococcus carriers and 98 per cent. of all who developed streptococcus-pneumonia belonged to the healthy carrier class.

After the influenza epidemic we undertook work involving a total of 160 separate experiments with a view to ascertaining by laboratory methods just how much contamination of the hands and mess gear could occur. We found that in warm weather, when a number of men wash their hands in warm clear water for thirty seconds, each man contributes 50,000 organisms; and in cold weather 200,000. If warm soapy water is used this number increases to 4,000,000 on warm days, while on cold days the number is 240,000,000. This increased contamination in cold weather is accounted for by the excessive contamination of the hands with organisms from the nose and mouth, this due to increased coryza, sneezing, and coughing. We believe that the increased prevalence of the so-called respiratory diseases during the winter months can be accounted for by the increased mucous secretions during that period.

Early we also succeeded in isolating streptococci from the hands of streptococcus carriers. This condition of course indicates the danger of the contamination of inanimate objects by sick or carriers. A further investigation involved some hundreds of examinations of the hands and eating utensils of sick and of carriers, and of inanimate objects, and showed the following results:

	Dishes per cent.	Hands per cent.	Inanimate objects per cent.
Streptococcus hemolyticus	84	38	13
Pneumococcus	63	17	50
Streptococcus viridans	65.6	100	26.6
B. Diphtheria	1.9	5.5	2.7
B. tuberculosis		1.8	

We were unable to find the streptococcus in air at a height of over 2 feet from the floor, but many streptococci could be found in the floor dust.

Tubercle bacilli were obtained from the hands of 45 per cent. of open cases; from the hand-washing water in 35 per cent., and from the rinse water in which their dishes had been previously hand washed in 25 per cent.

About this time it occurred to us that perhaps common dish water in public eating houses is responsible but to a less extent than mess kit wash water in the army for the spread of mouth-borne diseases. Therefore, 54 specimens of dish water from ten different restaurants were examined. They showed the average bacterial count to be four million per c.c.—approximately 50 times greater than sewage. But we recovered twelve million organisms from the ladle of a spoon used by a streptococcus carrier and many of these organisms were streptococci. A spoon may be contaminated with the culture of common organisms, then dried and washed with eating utensils in the usual manner, and then identified by the original contamination which had adherred to it during the washing process. We discovered later in 98 examinations that 78.82 per cent. of organisms were removed by hand washing, while machine washing removed 99.17 per cent.

One of the most interesting of our experiments to my mind was the one on transmission made by Colonel Cumming and Captain Cox at the Port Laboratory, Newport News, Virginia.

Before describing it, it might be well to summarize the exact steps in the transmission in the saliva-borne infections through mess-kit wash water. It is of course well recognized that in this

group of infections the saliva is heavily laden with the infectious virus or organisms. In making a transfer of these organisms through mess-kit wash water, the infected individual, presumably the mild, unrecognized case, contaminates his hands and his mess kit with these mouth-borne organisms. Consequently, in the washing process, the organisms from the mess kit and the hands are washed into the lukewarm water which does not destroy them. In the case of the donor then, there are two avenues by which the mouth organisms are introduced into the wash water—one through the contaminated mess kit, and the other through the contaminated hands. The wash water serves as a central focus of distribution after it becomes contaminated by unrecognized cases or carriers. Here again the distribution from the contaminated wash water to healthy men is through the contamination of both mess kits and hands. The contaminated mess kits and hands both go to the mouth, where the infectious virus or organisms are planted. Thus we have a two-link chain for the donor which is connected with the two-link chain of the recipient through the intermediate link formed by the mess-kit wash water. In carrying out this series of transmission experiments many preliminary tests were made, and finally a series of experiments which involved both donors and recipients was carried out.

Ten men were used in this experiment. Prior to each of six successive meals, the throats, mouths, and lips of five of these men (donors) were sprayed with a suspension of *B. prodigiosus*. After each meal these same men washed their mess gear in one gallon of warm water. The hands were used as mops in the washing process. Then, after the washing process had been completed by the five sprayed men, the five unsprayed men (recipients) likewise washed their mess gear in this same dish water.

In the examination of donors, that is the men whose oral cavities had been infected with *Bacillus prodigiosus*, it was found that 33 per cent. of their hands and 16 per cent. of their mess kits had become contaminated with the organism. It was next found that 66 per cent. of the mess-kit wash water specimens used by the donors were contaminated with this same organism. In investigating the recipients who used the same contaminated wash water for washing their mess kits, it was found that 45 per cent. of their hands became contaminated, and finally that the *Bacillus prodigiosus* was transferred to the oral cavities of these recipients by the hands and mess kits in 30 per cent. of all the examinations. Thus it is shown that organisms inoculated into the mouths of men can be transferred through lukewarm mess-kit wash water to the mouths of other men.

These results are wholly corroborative of our previously advanced theory of transmission through warm mess-kit wash water, and of the paramount importance of the use of boiling water as a means of closing the major avenue of saliva-borne disease distribution.

Figures are not available to me in regard to the influence of clean mess-kit washing and clean hands, or the reverse, in the recent small epidemic of influenza. I have been privately informed that at Camp Devens, Mass., where great interest is manifested in the subject, not a single death occurred last winter.

You will perhaps be surprised to learn how difficult it is to insure the sanitary washing of mess kits in the army. It may be admitted at once that it takes some trouble, but there is no sanitary procedure known to me compared with which an insanitary one under like circumstances would not be less troublesome for the time being. Who will take the trouble is another matter. Machines can take it all in permanent camps or posts. In the field it is up to the individual soldier to a great extent just as is the case with field sanitation generally.

I should point out that the situation in the army during this past year has not been one lending itself either to valuable research or to the best sanitary demonstration. But the Surgeon General has not been unmindful of the army's possibilities for learning how to control respiratory diseases. He has appointed an Advisory Board for this purpose.

While Doctor Wynkoop informed me, in inviting me to be present to-day, how very large a percentage of the Syracuse medical alumni saw service during the World War, I would have felt hardly justified in discussing my present subject if it had only military interest. As a matter of fact, it has no less interest for civil communities. Against pneumonia, the captain of the men of death, neither the civilian nor the soldier has a defense except that accorded by the observance of certain sanitary laws, and these laws must be directed against this disease, and not general laws which answer for other diseases. For example—what possible effect can the Imhoff tank have in the control of pneumonia? We believe we have found what should be done to prevent pneumonia in civilian and soldier alike. The civilian, it is true, does not use a mess kit, nor does he usually belong to a large messing group. Therein lies his comparative safety, but on the other hand, we all know that pneumonia often attacks more than one member in a family. Very likely this is through poor dish washing at home, or possibly through contaminated hands.

If one indulges in group messing, large groups, as in a restaurant, he is in a position of a soldier who uses table ware. The safety of each depends on proper pasteurization of the dishes. The mess-kit soldier, in our opinion, is always worse off than the civilian. This is a war danger that is much less thought of than bullets but is none the less real for all that. The wise commander and his soldiers by intelligent action can much diminish this danger, save under exceptional conditions in the face of another enemy. The civilian does not have this reason for not minimizing it. His enemy is a relentless disease. Like a good soldier he should not fear his enemy, but at the same time he should, as a matter of good judgment and common sense, take due and intelligent precaution to insure himself the victory.

I trust if I have made no converts to our theories, I have at least commanded your interest to a sufficient extent to induce you to study this subject carefully with our experiments in mind. No one realizes better than we do the magnitude of the problem or that additional work is demanded.

EPIDEMIC ENCEPHALITIS.*

By IRVING H. PARDEE, M.D.,
NEW YORK.
ASSOCIATE PHYSICIAN TO THE NEUROLOGICAL INSTITUTE.

No disease has so taken the medical profession by surprise as epidemic encephalitis, for it arrived here in the wake of the influenza epidemic almost unheralded. Its expected recurrence this winter makes its consideration still a matter of extreme importance.

Like most of the epidemics of the past decade, it has travelled from East to West, originating somewhere in that center of disease, Southeastern Europe, whence came poliomyelitis, influenza, meningitis, and lastly encephalitis. The accepted terminology for the disease has become epidemic encephalitis because the term encephalitis lethargica is incorrect and misleading. For, as it has been aptly said, it is not the encephalitis which is lethargic but the patient and when lethargy is present in only a small proportion of the cases, is it not a mistake to consider that the disease and lethargy are inseparable? A word of caution against the use of the term "sleeping sickness"; the tsetse fly in Africa has usurped that name for its own and trypanosomiasis is clinically a different disease from encephalitis.

The first report on the disease was by von Economo from Austria in 1917. He gave an excellent description of the clinical aspects and pathology of the disease and was the first to name it encephalitis lethargica. After that reports filtered in from Germany, later from France, and soon afterward a wealth of material appeared from England. In the fall and winter of 1918-19 the disease made its appearance in the United States in epidemic form, lasting until the spring. After that sporadic cases occurred until the first of this year, when it again appeared in large numbers and in a greater variety of forms than in the previous year. It has now spread to Latin America and the Orient, therefore becoming world-wide in its distribution.

Let me impress upon you that this is not a new disease. A study of the literature shows that an epidemic "sleeping sickness" was reported in 1712, again in 1745, and in 1800, and in 1890 the predilection of the influenza toxin for nervous tissue was noted by Leichtenstein in a splendid monograph and an encephalitis was described by him coincident with the great influenza epidemic of that year. Since then there have been described various encephalitic syndromes whose etiological factor was unknown and of sporadic occurrence. (Strumpell's "Primary Acute Encephalitis," Wernicke's "Polioencephalitis Superior Acute," and Leichtenstein's "Post-influenzal Encephalitis," etc.) However, to the younger generation of medical men the occurrence of encephalitis in epidemic form is a disease of considerable novelty.

Etiology.—Almost any age may be attacked, the disease having been reported in an infant four weeks old and in a man over sixty but, like influenza, it seems to strike particularly young adults between the ages of twenty and thirty-five.

*Read before the Medical Association of the State of Maine, July, 1920.

The sexes seem to be equally susceptible; one fact of interest is the large number of reports of pregnant women developing the disease who seem to be particularly liable to the infection, as they are to influenza.

There is a seasonal occurrence, the epidemic in each country reaching its height in the winter with sporadic cases appearing through the remainder of the year, most rarely in summer. During the past winter in New York the medical wards of all the large hospitals contained from five to ten cases all of the time, the disease being especially prevalent during January.

There is a special susceptibility on the part of the present generation to the invasion of what is to them a new disease. At its outset the cerebral forms were encountered, but this winter a greater variety of new types, notably those in the spinal cord, were seen; whether this has to do with the attenuation of the organism it is impossible to say.

The etiological factor is unknown. Several organisms have been reported, namely a diplostreptococcus by Von Wiesner[1] and others, and a "globoid" organism by Strauss and Loewe.[2] The latter investigators have carried out successfully inoculation experiments into monkeys with nasopharyngeal washings, brain tissue, and spinal fluid, and have reproduced the disease from the cultured organism. Recently Levaditi and Harvier have reported similar success.

The mode of transmission is supposed to be through the nasopharynx. However, its appearance in such large numbers in such widely separated localities almost simultaneously makes one feel that perhaps atmospheric conditions may disseminate it.

The question of communicability is an interesting one. There have been cases reported of a father and son contracting the disease, and a member of the house staff of a New York hospital died from the disease after having had several cases under his immediate charge. In spite of these incidences, which of course do not prove the point, neither at the Neurological Institute nor at the general hospitals in New York are these patients separated from the others, and no contact cases have as yet been reported from them.

Pathology.—In discussing the histopathology, I should like to lay emphasis upon the disproportion between the severity and extent of the signs of encephalitis and the slight changes found in the brain on necropsy. Many cases with signs indicating profound disturbances of the brain stem and encephalon will show macroscopically almost nothing and microscopically very little. In a very small number the reverse is also true.

In general it may be said that the toxic factor in encephalitis has a predilection for the grey matter; the most extensive changes are found in the basal ganglia, nuclei of the brain stem, and the floor of the fourth ventricle and aqueduct of Sylvius. Lesions have also been found in the posterior roots and the cranial nerves with resulting radiculitis and neuritis. The most characteristic lesions to be found in encephalitis are a perivascular infiltration and microscopical hemorrhages usually occurring from the venules. Mononuclear and plasma cells are seen invading

the tissue spaces about the blood vessels and edema is also encountered. Neuronophagia and engorgement of the pia mater are relatively mild in encephalitis in contradistinction to poliomyelitis.

Symptomatology.—General symptoms: The antecedent history of a previous catarrhal or grippe infection is obtained in a small percentage of cases, and some have followed an influenzal pneumonia. Most commonly the onset of the disease is acute without previous infection, and is ushered in by chills, lassitude, malaise, headache, anorexia, and fever, and differs very little from the onset of any acute infectious disease. However, the occurrence of a diplopia, dizziness, or delirium, and the signs of a localizing cerebral or spinal lesion soon serve to differentiate it from other conditions. There are mild forms of the disease which are never severe enough to put the patient in bed; the diagnostic points are few and may often be no more than a transient oculomotor palsy, or perhaps a slight drowsiness for a week or ten days, which may not even have made the patient stop work. The severe fulminating forms of encephalitis are rarely seen, but when they do occur the picture within ten or twelve hours from the onset will consist of vertigo, vomiting, and collapse, perhaps a convulsion, and then the signs of a severe involvement of the brain stem, as evidenced by paralyses of the limbs, cranial nerve palsies, delirium and coma following rapidly upon one another to death.

The temperature in the great majority of the cases is increased; in the average varying from 100° to 102°, subsiding gradually until by the fourth or fifth week it is gone. Fever is occasionally absent in the mild form and in the fulminating and fatal forms is apt to become very high. Hyperpyrexia is sometimes extreme, probably from a lesion in the temperature regulating center in the medulla.

The pulse commonly corresponds to the temperature and in a few cases a tachycardia of 140 to 150 is seen.

The headache accompanying encephalitis is seldom troublesome, and usually occipital in location. When severe it is apt to be due to an involvement of the posterior nerve roots at the highest cervical level.

Skin rashes, especially herpes, have been mentioned in some reports.

Photophobia is present and in a hiccough we have evidence of a phrenic nerve affection. In connection with this latter sign, I should mention an epidemic hiccough[8] which developed before and during the outbreak of encephalitis, both in this country and abroad. A few of these cases eventually developed evident signs of encephalitis.

Special symptoms: Having sketched the picture presented by the abortive, the usual, and the fulminating forms of encephalitis and having detailed the general symptoms, I will take up the remainder of the symptoms and physical signs in conjunction with their localizing centers in the cerebrospinal axis. In that way perhaps we may avoid attempting the impossibility of classifying definite fixed types of this disease—a very futile thing to do because of the diversity of localization in each individual patient.

The most evident symptoms of involvement of the encephalon are the mental attitude and status of the patient. Lethargy, which was at first thought to be present in all cases, is absent entirely in more than half of them. When present, it may vary from slight dullness and apathy to coma. At the outset patients may fall asleep during the day, or they may have prolonged hours of sleep; later in the course of the disease they may with difficulty be kept in conversation for any length of time and be quite somnolent. The impression they give of somnolence is often erroneous, presenting a picture of relaxed facial expression and a ptosis of the eyelids, but they are easily aroused to answer questions or enter into conversation, following upon which they will relax to their apparently stuporous condition. Such a patient may even complain of insomnia. The cause of this peculiar lethargy which accompanies encephalitis has been variously described as a toxic action upon the cerebral cortex or an interference with the corticothalamic sensory tracts.

Many of the patients in the febrile stage of the disease, excepting those with pain, are in a pleasing *euphoric* state, no matter how seriously ill they are. Delirium is also commonly seen and takes the form of the occupational type, rarely developing into an acute mania. It often simulates the muttering delirium of the third week of typhoid. Irritability, restlessness, mental depression, and anxiety are also seen. Aphasias of mixed types, catatonic states, and catelepsy are occasionally observed; especially noteworthy is the frequency with which we are now seeing mental disorders as residua of the disease; these may be paranoid states, expansive episodes of a paretic type, depressive psychoses, and many psychoneurotic states.

Next to the oculomotor and cortical symptoms those referable to the basal ganglia are the most important. Here there are four sets of symptoms comprising: (1) the Parkinsonian syndrome, in which is seen the mask-like unemotional facies, rigidity of the muscles, and flexed attitude of the body with stooping, the slowness of movements, and a tremor of a coarse oscillatory type suggesting though not always quite characteristic of the "pill-rolling" tremor of paralysis agitans, this may be unilateral or bilateral; (2) Wilson's syndrome of extreme spasticity of the limbs with involuntary smiling, indicating lenticular degeneration; (3) Choreiform and athetoid types which also may be limited to one-half of the body; (4) an involvement of the internal capsule or of either the pyramidal tract or lemnisci will result in hemiplegias, monoplegias, hemianesthesias, or hyperesthesias; rarely a hemanopsia has been observed.

Midbrain lesions are by far the most important and may involve any of the oculomotor nerves, paresis or paralysis of the third, fourth, and sixth nerves being seen either singly or in combination. Accompanying the diplopia and ptoses are seen interesting changes in the pupils; they may be unequal, irregular, and react sluggishly, or are fixed to light and accommodation. In no other disease than cerebrospinal lues is this condition so frequently found. A typical Argyll-Robertson pupil, however, is very rarely seen.

When the disease affects the pontine and bulbar region the syndrome is like that of a polioencephalitis inferior acuta. Trigeminal neuralgia perhaps with herpes indicates a Gasserian ganglion involvement, and anesthesia over its peripheral distribution has been noted. A bilateral or unilateral facial paresis may be present, but this must be differentiated from the Parkinsonian mask. Facial tics are often seen. The eighth and eleventh nerves have not been affected in my experience, but dysarthrias, dysphagias, and extreme tachycardia were noted late in the disease, indicating ninth and tenth nerve lesions. A thickness and slurring of the speech, and deviation or hemiatrophy of the tongue frequently occur and are evidence of lesions of the hypoglossal.

Convulsions have been seen of either the grand mal or Jacksonian variety.

The occurrence of symptoms of cerebellar involvement in the disease is more common in children and is evidenced by acute ataxias, asynergy, hypotonicity, and nystagmus.

Our first conception of this disease was essentially a cerebral one, but during the past winter we have observed frequent evidence of the involvement of the spinal cord. I should like to place particular stress upon the cases showing symptoms of posterior root disease; the radicular types which I have reported elsewhere[4] are characterized by myoclonic twitchings, hyperesthesia, paresthesiæ, and severe lancinating radicular pain. This may occur in isolated areas, such as the face, abdominal muscles, or arm, or it may progress in a descending fashion from the highest cervical to the lowest sacral segment. Carnot and Gardin[5] have reported an ascending myoclonic form. Herpes zoster has also been noted (Tilney and Riley[6]). Localizing symptoms in the brain may or may not accompany this type.

Involvement of the anterior horn will result in a clinical picture simulating an acute muscular atrophy. This is rarely seen, as are those types showing signs of a transverse myelitis with marked sensory impairment below the level of the lesion in the cord.

The relative infrequency of evidences of meningeal inflammation is noteworthy and is shown by the lack of headache, the rarity of stiff neck and Kernig's sign, and the low cell count in the spinal fluid.

In this connection I will mention also the rarity of choked disc. It is sometimes seen though and when pappiloedema occurs along with localizing symptoms of a cerebellar, brain stem, or cortical lesion, it is most confusing for diagnosis, and only the presence of an epidemic saves the patient from a decompression operation for brain tumor.

Sphincter involvement is not usually seen until late in the course of the disease and accompanies an increasing coma.

Before closing the discussion of the symptomatology, I should like to lay emphasis upon the marked asthenia, the low blood pressure, and the brachycardia which occur in these patients as the disease advances toward convalescence. This is an evidence of a vagotonic adrenal complex, a hypoadrenalemia, from the toxic effect upon the suprarenal glands.

Clinical Pathology.—The condition of the spinal fluid has been one upon which little stress has been laid. Probably about 70 to 75 per cent. of the cases will show pathological changes of some variety. The fluid is clear, and no film forms on standing. The cell counts in my experience have varied from zero to as high as 250, the usual range being from ten to seventy. An increase of globulin is observed in a greater percentage of cases than an increased cell count. Wassermann reactions have been uniformly negative, but the colloidal gold test has in many cases shown curves which are identical with either that of paresis or that of cerebrospinal lues.[7] The most frequent curve encountered would be represented by 1 1 1 2 1 1 0 0 0 0, or the so-called "irritation" curve. In a recent paper C. Dopter[8] has presented some interesting figures upon the inceased sugar content of the spinal fluid in encephalitis. This is a fact of considerable importance and may prove to be a differential point of value in diagnosis.

The blood may show a slight leucocytosis and a polynucleosis. One observer has noted an increase in the non-protein nitrogen, but otherwise the blood chemistry has been little studied.

The urine does not show evidence of any characteristic changes other than the usual febrile urine.

Course and Prognosis.—The tendency in the disease is toward chronicity, the majority of the cases extending over several weeks to months. A fatal termination may, however, occur within 24 hours or not until after eight or nine weeks. As the epidemic becomes more and more past history the chronic lesions are becoming a matter of greater concern to those of us who have given hopeful prognoses. Certain of the manifestations of the disease have a special tendency to become chronic. These are the Parkinsonian, psychotic, and a few of the oculomotor disturbances. The mild types are apt to have a short and uninterrupted convalescence, while the rapid and more severe types tend to relapse to chronicity. The prognosis for life in encephalitis is good. Recoveries occur in from 65 to 90 per cent. of the cases, varying with different reports. The prognosis in children seems to be better than in adults, and one author, E. L. Hunt,[9] notes that in cases with spinal fluid in which a cell count is very low or very high, the outlook is unfavorable, while intermediate counts of 40 to 60 offer a better prognosis.

Differential Diagnosis.—There are four diseases which epidemic encephalitis tends most to simulate, viz.: botulism, poliomyelitis, tuberculous meningitis, and brain tumor. The English observers in 1918 considered encephalitis to be an epidemic of botulism. In many characteristics, especially the ophthalmoplegia, they are similar, but we now are able to differentiate them. The absence of acute gastrointestinal disturbances is of importance in differentiation, also the absence of an epidemic.

Poliomyelitis differs from epidemic encephalitis because it occurs mostly in children and in the summer time; flaccid palsies are rare in encephalitis, and the extreme acuteness of both the cerebral and spinal forms of poliomyelitis is seldom found in encephalitis.

We find differentiation from tuberculous men-

ingitis often fraught with the greatest difficulty. The chronicity of tuberculous meningitis, the marked meningeal irritation, the increased tension of the spinal fluid, and lastly the presence of the tubercle bacillus will help us to a correct diagnosis; from the clinical aspect alone it is often impossible.

A certain few cases will in every particular simulate a brain tumor, as I have already mentioned, showing papillo-edema, vomiting, headache, and localizing signs. I well remember a patient who was seen in January by the best consultant in internal medicine and two leading neurologists of New York and whose case was diagnosed as one of frontal lobe tumor, in whom complete and permanent recovery occurred.

Cerebrospinal lues may simulate encephalitis. However here the serology will easily clear the diagnosis.

Still other diseases which may more rarely confuse the differential diagnosis are typhoid fever, uremia, paralysis agitans, Sydenham's chorea, the delirium of acute infectious diseases, hysteria, and the various psychoses which it may simulate.

Treatment.—The treatment of encephalitis is entirely symptomatic, for as yet no specific remedy has been found. During the acute febrile stage the patient should be in bed on a fluid diet. Elimination is of importance, fluid being forced by mouth and by rectum if necessary. Colon irrigations have been advocated. Should the fever be high, cold sponges may be used to bring it down and also allay restlessness. For the insomnia and delirium medinal or veronal and bromides or paraldehyde may be given. For the severe hyperesthesia and radicular pains the cold tar drugs help, but codeine and morphine are usually necessary.

Hexamethylenamine is frequently given because of its supposed bactericidal effect on the cerebrospinal system. A method of approach upon which A. Netter[10] lays emphasis is the production of a fixation abscess by the injection of 1 c. c. of turpentine, the improvement resulting being obtained from a stimulating action on those organs which provide the natural means of defense. This theory is not yet an accepted fact. The intraspinal injection of convalescents' serum is a procedure which has been attempted, but so far antibodies for the virus of encephalitis have not yet been demonstrated in the blood. Further effort promises more specific results with this therapy than along any other line. Repeated spinal punctures, as in other types of cerebrospinal disease, have also been found to have a beneficial result from their drainage effect.

The convalescence of encephalitis is apt to be prolonged. A partial rest cure must be prescribed for the patient and the marked asthenia which I have mentioned should be combated with suprarenal gland, gr. 1 to 5, t.i.d. General hygiene must be excellent to bring about the most rapid recovery.

In the residual paralyses and contractures, massage and galvanic electricity will give the most comfort to the patient and the best functional result.

THE MENDELIANISM OF MIGRAINE.

BY J. ARTHUR BUCHANAN, M.D.,

ROCHESTER, MINN.

FELLOW IN MEDICINE, THE MAYO FOUNDATION.

THE conception that disease is hereditary seems to rest on the consideration that it is hereditary provided it occurs in parents and their children. This belief is strictly out of accord with the laws of heredity as originally exemplified by Mendel, and by innumerable investigators since the publication of Mendel's observations in 1865.

A disease is understood to be hereditary when it is transmitted as an integral part of the male or female germinal cells to the product of the union of these two cells. Heredity can occur only through the medium of the chromatin and the cytoplastic structures of the germinal cells and conditions that are hereditary are transmitted from generation to generation in a fairly definite numerical ratio. The determiners of the transmitted characters are constant.

The first law of heredity, and the one with which any disease must comply if it is to be considered hereditary, is known as the segregation of characters or the law of numerical distribution of characters in the products of a mating. This law makes it necessary that the determining factor of a disease shall be present either actively or inactively in one or the other parent. Among the products of a mating the ratio between those with the disease and those without it can be ascertained only by a statistical tabulation of the offspring.

Migraine is one of the most common affections of man. It was considered hereditary even before Mendel published his observations. The belief that migraine is hereditary rests apparently more on a traditional than on a statistical basis, but this is not to be wondered at when it is recalled that an active controversy exists with regard to the actual reality of migraine as an entity.

In order that no confusion may arise, the term migraine, in this study, labels an affection characterized by paroxysmal attacks of pain, usually in the head, either unilateral or bilateral, but occurring also in the abdomen and associated with nausea, vomiting, mental depression, disturbances of sight, and many vague somatic disturbances. One or all of the symptoms may occur in an attack. The affection starts in early life, and as a rule terminates during the fourth decade.

During the year 1919, 1,300 persons (2.1 per

cent. of the total registrations) were examined at the Mayo Clinic who fulfilled the foregoing requirements for migraine. Of this number 127 families were studied and the data obtained are as follows:

1. At least four offspring from each mating.
2. Definite notation of the presence of migraine directly or indirectly in parents or near relatives.
3. Total number of children with and without migraine in each family.

A clear conception of what is to be expected from an affection that fulfills the law of the segregation of characters can be secured by a brief review of the behavior of plants and fowls.

Example 1.—The study of the transmission of the character's tallness and dwarfness in the edible pea gives a clear illustration of the numerical ratio of the Mendelian phenomenon. If a tall pea is crossed with a dwarf pea the hybrid is tall. By breeding the tall hybrid three tall and one dwarf are obtained. Of the talls one always breeds true to tall, and two talls always breed three tall to one dwarf. The dwarf always breeds true to dwarf. This process is kept up indefinitely so that from each generation one pure dwarf and one pure tall, and two talls which have concealed within them the ability to produce both tall and dwarf are always obtained.

The ratio of 3 to 1 is only approximate, as Mendel in his observations found in a series of 1,064 plants that there were 787 tall plants and 277 short, or a ratio of 2.84 to 1. In the study of color of seed coats Mendel found that among 929 plants 705 bore violet red flowers and grey brown seed coats; 224 bore white flowers and white seed coats, giving a ratio of 3.15 to 1. The exact ratio of 3 to 1 is rarely seen in plants or animals.

Example 2.—The transmission of characters in fowls is illustrated in the Andalusian fowl which is blue; by crossing it with another blue fowl, the result is always one black, two blue and one white. The black always breeds black. The white always breeds white. Crossing the black with the white results in blue offspring; this demonstrates the Andalusian fowl to be a hybrid.[3]

With these simple examples in mind as an expression of the Mendelian phenomenon, a study of migraine gives striking figures:

Study I. Mother or Father with Migraine.—This group comprised the offspring of 100 families made up of 143 children with migraine and 488 without migraine or a ratio of 3.13 to 1.

Study II. Parents with Migraine with Epileptic Offspring.—This group was made up of seven families giving a total of ten children with epilepsy alone or a migraine-epilepsy syndrome and thirty-seven children without migraine or epilepsy. This gives a ratio of 3.7 to 1. The relation of migraine to epilepsy was brought out in a previous study in which it was found that 75 per cent. of the patients studied had migraine as either an ancestral or a personal history. The relation of migraine to at least one type of epilepsy must be very close.[1]

Study III. Crossing of Persons with Dormant Migraine.—Under this heading seventeen families were tabulated in which the migraine was not present in the father or mother of the family studied, but was present in brother, sister, father, or mother of the parents of the family studied. In this group thirty children had migraine and eighty-five did not have migraine, or a ratio of 2.83 to 1. It is our purpose to investigate further the ratios which result from the mating of a person without migraine with one who has dormant migraine, or a person with true migraine with one who has dormant migraine. The occurrence of these crossings gives unusual ratios in families and unless this is borne in mind migraine may not be considered a true Mendelian character.

Study IV. Parents with Migraine.—Three families were found in which the presence of migraine in both parents was carefully investigated. The total number of children born was fifteen, and, as might be expected from the crossing of two pure types, all had migraine.

The total number of children in this study was 198 with migraine and 610 without migraine, giving a ratio of 3.08 to 1. This tabulation places migraine in the Mendelian ratio, and definitely establishes the hereditary nature of the affection.

The conception of migraine as an hereditary character has an important bearing on the therapy of the affection. Surely no one could hope to modify by therapy an hereditary character which is as definite a part of the economy of a person as the color of his eyes. It could not be hoped to alter or modify the course of migraine by cerebral decompression, cholecystectomy, gastroenterostomy, colectomy, appendectomy, unilateral or bilateral oophorectomy, salpingectomy, partial or complete hysterectomy, or any of the many other operations of greater or less magnitude which have been and are still being performed on the patient with migraine. If such operations have not helped the patients, they have at least shown that surgery has nothing to do with the treatment of the affection.

Summary.—Migraine is a distinct type of disease, and should be easily identified after the appearance of the symptoms. The disease is an expression of the Mendelian phenomenon with a ratio of 3.08 to 1; there is no medication known that will alter its course; it is a distinct part of the patient's economy, and it will have no harmful influence on longevity.

NASAL DEFORMITIES DUE TO THE SUBMUCOUS OPERATION, THEIR PREVENTION AND THEIR TREATMENT.

By WILLIAM WESLEY CARTER, A.M., M.D., F.A.C.S.,
NEW YORK.

IN view of the great popularity of the submucous operation for the relief of nasal obstruction due to deflected septa, and on account of the increasing number of depressed nasal bridges due to this procedure that are coming under my observation for operative correction, I feel that a communication upon this subject will not only be timely, but that it may be of distinct value both to the general prac-

titioner and to the rhinologist as a reminder that disagreeable results may and do follow this operation when it is performed without taking into consideration the age of the patient and without due regard for the anatomical and architectural structure of the nose. I trust, too, that my suggestions may serve to protect from undeserved discredit an operation which, when properly performed, is one of the most artistic and useful procedures in the field of rhinological surgery. The conditions prompting me to throw out this warning are not fanciful, for no less than twenty-six cases of depressed nasal deformity, due to the submucous operation, have come to me for correction, and I have seen several others in the practice of other men. In none of the cases to which I refer was the deformity due to infection introduced at the time of the operation, it was due either to the operation having been performed at too early an age, or to the destruction of the integrity of the nasal arch by interference with its architectural structure. I am happy to say that this accident has never occurred in my own practice, though I have to my credit many hundreds of submucous operations. In view of this experience, I feel that I am fully justified in attributing to the methods I employ and which I have always advocated, the immunity I have so far enjoyed from having my operations followed by sunken-in bridges and a general weakening of the architectural structure of the nose.

The nasal arch is subject to the same mechanical laws that govern any other arch. It is a curved structure composed of an indefinite number of segments so placed that it may be supported at its two extremities. The growth of the nasal septum is a prominent factor in the development of the arch, and its presence strengthens it, but as a vertical support it takes only a minor part in the preservation of its integrity. The upper edge of the septum, however, wedged in as it is between the upper lateral cartilages, constitutes the keystone of the arch, and if by operation, accident, or any other influence this keystone is displaced or destroyed, the dorsum of the nose falls in and the nasal arch is established on a lower level. The problem at first is purely a mechanical one; the deformity, however, is later increased by the formation and contraction of scar-tissue and by the elasticity of the skin of the face. Once the keystone has been destroyed, the deformity resulting can be corrected only by the transplantation of bone or cartilage. The method by which this is done was devised by me several years ago and has been previously described. The results I have secured in these cases have been excellent; not only is the nasal arch restored to its original strength, but even the flexibility of the tip is preserved by using a transplant composed of conjoined cartilage and bone—a refinement in my technique which I introduced several years ago. I may say here that the promise of relief from the deformity following an unwisely or unskilfully performed submucous operation is no excuse for the employment of lax or unsafe methods.

One of the most important considerations in connection with the submucous operation, if not the most important, is the age of the patient; and yet this is frequently ignored by the surgeon in his enthusiasm to relieve a distressing nasal obstruction in a child. I quote from a paper read by me before the New York Academy of Medicine on April 26, 1906, and published in the *Laryngoscope*, June, 1906: *While I am convinced that the septum as a vertical support takes no part in the preservation of the contour of the nose, I am equally certain that it does take a most important part as one of the forces in the development of the symmetrical adult organ, and therefore should not be removed during the years of most active growth.* This warning of the dire results which might follow the resection of the septum in the young, appeared in the original in italics, and it is, so far as I know, the first recorded reference to this important subject. At that time it was purely prophetic and was based upon knowledge I had gained by studying the dynamics of nasal development, a subject which has greatly interested me for many years. I have since found ample justification for this warning in several cases of saddle-back nose brought to me for correction, where not the slightest doubt could be entertained as to their cause being the absence of the developmental influence of the septum.

This raises a question of great practical importance and one which we are called upon almost daily to decide, namely: What shall we do for the child suffering with pronounced nasal obstruction due to a badly deflected septum? This problem cannot be solved without a painstaking anaylsis of the case and a careful estimate of the relative advantage to be gained by the course pursued. The assumption is warranted that the septum cannot be straightened and the obstruction to nasal respiration relieved without an operation of some kind. My experience in nasal deformity work teaches me that in a child extensive destruction of the septum, such as occurs in the usual submucous operation, is certain to result eventually in a deformity of the nose. The character of this deformity varies only slightly in different cases:—the base of the nasal triangle is very broad, the bridge of the nose is flattened, and the concavity from above downward is uniform, the greatest depression being at a point corresponding to the ends of the nasal bones. In most of these cases the whole face eventually becomes broad and flat and for some reason, I know not why, there is a strong tendency to the early development of atrophic rhinitis. There are, therefore, a number of potent reasons why the developmental function of the septum in the young should not be interfered with. On the other hand the conscientious surgeon, though he has clearly in mind the dire results which may follow any operative procedure extensive enough to destroy this function of the septum, is equally impressed by the urgent necessity of relieving a bad obstruction to nasal respiration which, if long continued during the years of active development of the child, is likely to be followed by conditions not only objectionable from a cosmetic point of view, but what is of far greater importance, injury to the general health, due to deformity of the jaw resulting in malocclusion of the teeth, maldevelopment of the chest, mental dullness, etc. These important considerations leave in my mind no doubt as to the course to be pursued—the obstruction must be relieved with as little disturbance of the septum as possible.

In attempting the relief of these cases my object is to accomplish this as nearly as possible by

the replacement of the septum into its normal position. In order to do this it may be necessary to remove a small amount of cartilage and bone if there are spurs or if there is a marked bulging in the center of the septum.

The technique of the operation which I employ in these cases varies according to the location and degree of the septal deviation but the principles involved are the same. Before the details are decided upon, a careful study of the deviation must be made. The chief observations are whether the septum bulges at the center or whether the entire septum is displaced and lies diagonally, the upper edge being on one side and the lower on the other. We must note also whether the deviation is accompanied by spur formation. To me all intranasal operations are easier and I can carry them out more accurately and quickly with the patient conscious and in a sitting posture—that is if the patient is amenable and will sit quietly while the work is being done. It is unreasonable to expect this in any child of the age now under consideration, so it is better to employ general anesthesia in all cases.

Ether is the anesthetic of choice. When its administration is begun, I pack both nasal cavities with adrenalin 1-1000, and immediately before the operation is begun a few drops of adrenalin in physiological salt solution 1-5000 is injected hypodermically along the mucocutaneous junction and along the base of the septum.

We now proceed as if our intention is to do the usual submucous operation. My first and only incision is made along the entire septal mucocutaneous junction, extending it across the floor of the nose. Through this incision, if necessary, the mucoperichondrium is elevated over the entire septum on both sides. I use for this purpose my curette elevator. The instrument must be sharp, for the perichondrium is more closely adherent to the cartilage in the child than it is in the adult. Working through this incision with very small knives of various shapes and angles devised for this purpose, I reduce the septum to a vertical plane. I then place one of my paraffin splints on either side of the septum and pack both nasal cavities with vaseline gauze. A tin-lined copper splint, made to fit the nose, is then placed in position and kept on for about a week. During this time the nose must be inspected and if necessary dressed each day.

I have treated a number of these very puzzling and difficult cases in this manner and so far in no instance has a saddle-back deformity developed, and I regard this as the best method of dealing with marked septal deviations in the young.

The prevention of deformity in the adult following the submucous operation is chiefly a matter of avoiding infection and preserving the integrity of the nasal arch by exercising the greatest care not to displace or destroy the upper edge of the septum which is wedged in between the lateral cartilages, constituting the keystone of the arch. This upper strip of cartilage should be left as thick as possible, and, *regardless of the intranasal cosmetic effect, only those portions of the septum should be removed which constitute a menace to free nasal respiration.* In order to observe these precautions, it is necessary to use an instrument for the removal of the septum which does not drag and which removes a definite amount of the tissue from the exact location desired. No instrument is so satisfactory for accomplishing this as the punch-forceps. The instruments I devised for this purpose were described in the *Laryngoscope*, March 1916; I have made no modification in their construction, and am still using them with great satisfaction in my work.

Treatment.—The course to be adopted in the treatment of the depressed deformities resulting from the submucous operation, in my opinion, admits of no discussion; there is, so far as I know, only one satisfactory method by which they may be corrected, and that is by the transplantation of bone or cartilage by the method which I devised some fourteen years ago; or preferably by a combination transplant composed of both cartilage and bone, as first described by me in the *Laryngoscope* five or six years ago. I use in these cases a transplant from the ninth rib, composed of two-thirds bone and one-third cartilage; this is taken at the junction of the rib with the costal cartilage. The transplant is introduced from within the nose and no scar results. The full strength of the nasal bridge is restored and the repair is permanent, for some of my cases have been under observation long enough to demonstrate this fully. The bone transplant establishes a firm bony union with the frontal bone and supports the nasal bridge in its normal position; the cartilage preserves the normal flexibility of the nasal tip.

In conclusion I will say that while the number of deformities resulting from the submucous operation are few in comparison with the number of cases operated upon, still the knowledge that these deformities are serious in their import and that they may and do occur in the hands of unskillful operators and others when proper precautions are not observed, is sufficient justification for this presentation of the subject.

2 West Sixty-seventh Street.

AURAL AFTERMATHS OF THE INFLUENZA.

By ALBERT BARDES, M.D.,

NEW YORK.

The recent epidemic of influenza has been followed by more ear trouble than any previous epidemic of the kind. Ever since the first invasion of the grippe in 1890, the so-called grippe ear has been feared by physicians, both on account of the danger to life and because of the effect upon the hearing. In infants of tender age the grippe ear is often disastrous. The organ of hearing is the most delicately constructed mechanism in the entire body, not excepting the eye. In babies not only is the auditory apparatus extremely frail, but it is especially assailable, owing to the close connection between the nose and the ear, the Eutachian tubes in infants being relatively shorter and the caliber larger than in adults. Deaf-mutism is nearly always the result of ear disease in infancy. So delicate is a babe's organ of hearing that even a fall, boxing the ears, or throwing a child up in the air has been known to destroy the hearing.

Singular as it may seem, most ear infections from the influenza do not give trouble until the symptoms of the influenza are abating and the patient is apparently recovering. This is in the

second week, when the vitality is lowest and the recuperative power is in abeyance. Whenever symptoms of mastoid disease occur in the early stage of influenza, it is probable that the ear disease antedates the attack of influenza, the latter disease having simply rekindled smoldering embers. It is not unusual, when operating for mastoiditis, during an attack of influenza, to discover evidence that the disease has been going on for a long time. It takes time for pus to destroy bone and it is doubtful if bone necrosis can occur wtihin two weeks after the cells have become infected.

The middle ear is really an antechamber of the nose and often shares in nasal disturbances. In an attack of influenza the middle ear, in common with the nose, becomes intensely congested, and paves the way for disease. The healthy middle ear is a sterile chamber and difficult to infect. When infectious matter is experimentally forced into the middle ear, by way of the Eustachian tube, it is promptly expelled by the ciliated epithelium. In influenza, however, the various agents that ordinarily safeguard the integrity of the middle ear fail to functionate, and infection of the middle ear becomes an easy matter. The nose at all times harbors disease germs and these can readily gain access to the tubes by such expiratory blasts as sneezing, crying, coughing, or even blowing the nose. Infection from using the nasal douche is extremely common.

When the febrile symptoms of the influenza subside, the engorged mucous membranes of the upper air passages pour out their inflammatory exudate and a copious flow of mucous issues from the nose; generally to the relief of the patient. This is commonly known as the breaking up of the cold. Some of this secretion comes from the middle ear, and is apt to contain infectious germs. If for any reason the Eustachian tube—the drain-pipe of the ear—fails to functionate, the accumulating exudate soon fills the various compartments comprising the middle ear, especially the mastoid cells, and presently, by its pressure upon the drum-head, causes earache, than which no pain can be greater nor more significant of danger. Often the blockage of the Eustachian tube is but temporary. This accounts for those mild attacks of earache which are controlled by rest, and the application of heat or of cold, the symptoms passing away as soon as nasal drainage becomes re-established.

In infants the onset of an ear infection is usually sudden, owing to the active secreting function. The middle-ear fills rapidly. The child becomes feverish and fretful and declines food. It rubs the ear and refuses to lie upon it. There may be nausea, vomiting, and perhaps an irritating reflex cough. The infant whines rather than cries, because the latter act is more painful than the former. Accidentally touching the ear elicits a sharp outcry. When the pain becomes unbearable convulsions occur and the child becomes unconscious. Frequently the symptoms of a middle ear infection in a babe are so obscure and misleading that the attending physician is perplexed until the ear begins to discharge and discloses the seat of the trouble.

In adults the earliest symptoms of an infected ear are throbbing and fulness in the ear. Presently there are head noises, dizziness, and restlessness. Every movement of the head, and especially the jar of walking, increases the distress. Soon the hearing becomes dull and the feeling of discomfort merges into pain, which is worse at night and when lying down. Within a few days symptoms of mastoiditis supervene and intensify the suffering.

The only way to ascertain the true condition of the middle ear is with the ear speculum. Subjective symptoms may be misleading. Often the drum-head is hidden from view by some foreign substance, perhaps wax. Not infrequently the inflamed drum-head is covered with a whitish layer of exfoliated epithelium which disguises the membrane and deceives those not familiar with ear diseases.

A beginning earache should be treated with rest, fluid food, a saline laxative, and the ice-bag. If the pain fails to subside after six hours, the drum-head should be incised. In earache, as in appendicitis, prompt surgical measures are the most conservative ones that can be employed. Nothing is gained by waiting, for the danger and the distress become hourly greater. To wait for a drum-head to break as is often done, is a grave error. It is a course which has been attended by much unnecessary suffering and by many deaths. When we see some of the old spontaneous perforations with their sad results of chronic invalidism, we cannot but feel that one of the great boons conferred upon humanity is the timely incising of the drum-head. Pressure and pus are the basic factors in nearly all ear complaints and the sooner they are released the better.

Aside from the risk of waiting for a drum-head to burst, the opening made by nature is seldom all that can be desired from a surgical standpoint. It may be too small for adequate drainage, or, perhaps, it is too large or irregular and fails to close when the active discharge has ceased. Almost all the discharging ears that last through life can be traced to a spontaneous perforation.

Merely to puncture the drum-head, as is done in paracentesis, is inadequate for the escape of thick fluid, and often fails to confer relief. This operation has been discarded for the more thorough one of making a free incision under a general anesthetic. The incision should begin at the lowest part of the drum-head, extend upward behind the malleus, and terminate in the swollen posterior canal wall. In the right ear, the incision resembles the letter *z*; in the left the letter *s*. This procedure, the so-called internal Wilde incision, not only drains the middle ear freely, but it also depletes the congested area near the mastoid process, and encourages drainage of the mastoid cells.

Incision of the drum-head is rarely followed by the escape of pus. Generally only a few drops of serum are released. After a few hours, however, the discharge becomes copious and purulent, and the patient is eased. Even physicians often wonder where all the secretion comes from, considering the small size of the middle ear. As a matter of fact the secreting surface of the entire middle

ear has been computed to be larger than the palm of the hand. Usually the ear flows freely for a week. Then the discharge gradually abates and a week later it ceases entirely. Here again we note the merits of a clean incision for as soon as the discharge stops, the aperture in the drum-head closes and the resulting scar in no way interferes with the functions of the membrane.

In most instances, the moment the pressure within the middle ear becomes relaxed, the distressing symptoms ameliorate. Occasionally they do not, implying that drainage is imperfect. If symptoms of mastoiditis persist it is evident that the infected secretion within the mastoid cells is unable to escape. The mastoid antrum communicates with the middle ear proper, by means of a tiny aperture—the aditus—and this opening, besides being small, is unfavorably situated for drianage. It easily becomes occluded and then it causes retention of the septic contents of the cells and mastoiditis.

The severity of a middle ear infection is governed by the virulence of the infecting organism and by the resistance of the sufferer. The best time to examine the aural secretion for the offending organism is directly after the flow begins, for presently foreign germs from the exterior contaminate the discharge and the identity of the infecting organisms is lost. Discharge containing either diplococci or streptococci should be carefully watched. A frequent blood count is desirable, to note the course of the disease in relation to the blood current. Normally the general leucocyte count is about 8,000, of which 67 per cent. are polynuclear leucocytes. An increased leucocytosis, say 12,000, shows an active inflammatory lesion with good resistence. A leucocytosis of 6,000 indicates poor resistance. The polynuclear percentage is of great importance in these cases. When it rises to 80 it denotes an active septic process. This coupled with a low leucocytosis, shows a serious condition. After an operation, both leucocytosis and polynuclear percentage should return to normal. If they do not, it is evident that the progress of the disease has not been checked, and that septic absorption continues.

When a person has recovered from a middle ear infection, especially after the influenza, the ear should be examined and the hearing tested at frequent intervals. The formation of fibrous tissue is the last stage of all inflammatory lesions. In the middle ear, after the exudate has been absorbed, some fibrin is left behind. This is apt to produce adhesions between the movable parts, in the same way that a severe rheumatic infection of the large joints is followed by stiffness and ankylosis. Chronic progressive deafness is often the result of such adhesions. The oval window is the place where intratympanic adhesions do the most harm. This membrane, to which the stapes is attached, is of far greater importance than the drum-membrane. The sound-waves cause the oval window to vibrate, and for every excursion there is a compensatory movement of the round window. The condition of the oval window can be determined by means of the Gellé test.

Ankylosis of a large joint is overcome by massage and forcible movement, to sever and relax the adhesions. The same treatment in modified form is applicable to the middle ear. If it is neglected, the movements in the middle ear become restricted and a remediable condition lapses into an incurable malady.

Normal hearing can be likened to a curved line, which rises from zero at birth, reaches the crest at the completion of adolescence, and drops to one-third in old age. If the curve be deflected by disease, the subsequent line becomes depressed and shows premature loss of hearing. The otitis of influenza is especially apt to alter the normal contour of the curve.

This disturbing sequences of the influenza may not become apparent until months or even years have elapsed. It frequently happens that long after an attack of influenza, a patient comes to us complaining of head noises or of vertigo, nothing being said of the hearing. But when the latter is tested, it is found to be deficient. Normally we are endowed with twice as much hearing power as we require in ordinary usage, so that when a person does complain of poor hearing, it is probable that the defect is greater than anticipated. The higher degrees of hearing are not used to anything like the same extent as those of the eyes. For this reason a defect in hearing will pass unnoticed where a corresponding error in vision will attract attention. Many individuals with dim hearing derive consolation from the fact that they can hear well on the phone. They do not know that the sound is being conducted by the bones in the head and not by the air—a bad sign.

A running ear is one of the commonest and most troublesome aftermaths of the influenza. Not only is the discharge discommoding, but the condition is usually attended with poor hearing and head noises. The source of the discharge is an ulcerative lesion, either of the mucosa or of the bone. The longer the flow lasts the less amenable it becomes to treatment.

The difficulty often encountered in treating these cases is largely owing to the fact that the disease involves the attic, and is not easily reached. Generally, as soon as the tympanum has been cleared of foreign substances, the aperture in the drum-head will close. The drum-head possesses remarkable power in mending its defects with cicatricial tissue. Most holes in the drum-head can be repaired if we will assist Nature by stimulating the reparative process, either by incising the edges of the perforation or by freshening the edges with acid. All perforations, about to close, become round, no matter what their former shape has been.

Frequently, especially in children, a discharging ear cannot be brought under control until the nose and the throat have been restored to a healthy state, since these organs often supply the infecting material that keeps up the ear discharge. The removal of tonsils and adenoids in a person with a running ear, should be supplemented with the removal of granulations from the middle ear. The measure of last resort to stop a running ear is the radical mastoid operation.

Head noise, or tinnitus aurium, is an annoying complaint that often follows the influenza. It is

especially harassing to a person with a musical ear. The noise interferes with hearing and frequently it is the forerunner of deafness. The depressing effect of the noise makes certain individuals weary of life. I know of instances where suicide was contemplated. A noise may be but temporary, as from anemia, from drugs such as quinine and aspirin, from cerumen, or from alcohol and tobacco. The noise mostly complained of is likened to escaping steam. The sound may change and frequently a variety of noises are present. The noise seems loudest in a quiet place and in the recumbent posture. Any condition that dulls the hearing, such as illness, exhaustion, and damp weather, intensifies the noise. Whenever bone conduction is amplified, as in middle-ear disease, normal sounds within the body, hitherto unheard, often become audible. This applies especially to the blood circulating near the middle ear. A pulsating sound is of arterial origin, a low hum of venous. Most sounds of low pitch are suggestive of middle-ear trouble. Those of high pitch, of internal ear disease. Of course progressive middle ear disease finally involves the internal ear also.

The pitch of a subjective sound can be determined by holding a vibrating tuning fork of medium register, say a C^1 fork of 256 vibrations, close to the ear, requesting the patient to state if the head noise is higher or lower in pitch than the fork.

The vertigo that is often associated with internal ear trouble is very annoying and often dangerous. The sixth or static sense resides in the semi-circular canals of the internal ear and it controls the equilibrium. The least derangement of these tiny canals affects the balancing sense. Seasickness is caused by the agitation of the contents of the canals. The incoordination in drunkenness is due to the irritating effect of alcohol upon the tiny nerve filaments in the canals. Infants and deaf mutes seldom become seasick. In the former the sensitive mechanism in the canals is undeveloped. In the latter it is atrophied from disuse. The proper functioning of the organ of equilibrium is of great importance, especially to aviators, structural workers, and others engaged in hazardous undertakings that call for quick action and exact equilibration. Many aviators have met with disaster by flying directly after an attack of the influenza.

221 East Fifty-seventh Street.

VACCINES IN GENERAL PRACTICE.

By A. G. HUEGLI, M.D.,

DETROIT, MICH.

The general practitioner seems to think that vaccine therapy should only be employed by one who is especially skilled and trained in its use—in other words, by the specialist. This is decidedly erroneous. Vaccine therapy is here to stay, and it behooves the general practitioner to become thoroughly familiar with this new science of healing, for into no better hands can this new art be entrusted than into those of the man on the firing line—the general practitioner.

It is not my intention to go into a lengthy discussion of its theories, but I shall endeavor to present its practical application from my viewpoint, as a general practitioner. And I will start by saying that the citation of individual case-records is wearisome and valueless, although this could be done ad infinitum. Such action on my part would only call forth the timeworn argument of a patient recovering in spite of the treatment. The merits of any new therapy demand clinical evidence of a cumulative nature based on the experience of many investigators in like cases.

The use of vaccines does not preclude any proper surgical procedure, such as might be called for, for instance, in disease of the tonsil, of the bone, of the gall-bladder, or in pus accumulation, etc. Vacines are, however, strongly indicated when the patient shows unmistakably a continued impairment of vital resistance. It was believed, at one time that a careful opsonic index observation was imperative, but this entailed an extensive practice in a laborious technique, which, after all, proved irreliable on account of fluctuations in the activity of the opsonins.

Clinical observations will soon show to what extent immunity is being established. That a reaction of more or less degree follows the injection of vaccine should be anticipated, this in itself being an excellent guide. The physician should call his patient's attention to this expected phase, and should estimate the subsequent dosage and frequency of administration by succeeding manifestations, while experience shows that it is better to start with a small dose and gradually increase the same to the height of toleration, severely acute conditions tolerating large doses well.

The purpose of giving a vaccine injection is to establish an immunity against the rapid invasion of bacterial elements. Ordinarily where phagocytosis is normal and the invader is not too virulent, nor great in number, recovery takes place under established methods. On the other hand, take for instance a pneumonia case. Would I be justified to wait and see how phagocytosis was taking care of the pneumococcus and its concomitants? Would there be time to make a culture of the patient's own pneumococcus, prepare a suspension, and make the inoculation? Would not the undertaker have long superseded the doctor if he engages to make an autogenous vaccine? I am sure that your experience has taught you the impossibility of this and the exceeding rarity of cases permitting recourse to this step.

Now we have a corresponding stock vaccine immediately available and which may be relied upon, based upon innumerable applications to produce in a majority of cases an early, favorable reaction. This immediate accessibility to a standard stock vaccine is of immeasurable advantage and hardly leaves the adherents of autogenous vaccine debatable ground.

The United States Government has reduced typhoid to a negligible degree in its army and navy. It uses a stock vaccine. Why, then, should we hesitate to use stock vaccine in general?

Many objections are raised from sources "higher up" against the promiscuous use of mixed or polyvalent vaccines. It seems that it is rigidly expected of the busy practitioner to absolutely know what

particular germ is causing the abscess or the infection, and from experience he does know. He further knows that there are other species of germs involved. Who would venture to say that an otitis media was caused solely by one specie? Who would venture to say that he had an exclusive colon bacillus cystitis? Who would venture to say that the sputum of the tuberculous contained only T. B.? If it is the concomitant bacteria, which add in no small measure to the destruction of the living being, why not then use mixed vaccines?

On this subject I will quote Prof. John O. Polak, *Journal A. M. A.*, November 22, 1911, page 1739: "Autogenous vaccines of a single strain have given me unreliable reactions. This, I think, can be explained by the fact that the coccus is attenuated in its strength and, after it has produced is first reaction, the leucocytes become more or less accustomed to the particular variety of coccus, and are less liable to effect a defense than when a vaccine of polyvalent strain is introduced. Mixed vaccines of reliable laboratories have given better results than when a single variety was used. This has been shown repeatedly in the blood-picture when an autogenous vaccine of single strain used in large doses, even up to 500,000,000, has failed to increase the leucocyte count or diminish the polynuclear percentage, the mixed vaccines of several strains have promptly produced a marked leucocytosis. Even colon bacillus infections, such as infection of a pelvic hematocele by the colon bacillus, have yielded more promptly to mixed vaccines of polyvalent strains, than when a single autogenous germ had been used. One characteristic which has been noted throughout all of our experience is that, even before any definite effect has been noted on the temperature, the well-being of the patient has seemed to be improved by vaccine injection."

When a diagnosis has been established vaccines should be given early. It is surprising how readily your patients consent to be inoculated when the intent and purpose of the inoculation has been explained. It is a frequent occurrence for people to request the injection of a vaccine which cured them the previous year or two or three years ago.

Probably the most frequent ailment a physician is called upon to treat is the ordinary so-called "cold," or rhinitis. The affection is self-limited and runs a course of three or four days, but we all know what a cold may lead to. Now one injection of vaccine is cheap insurance against possible extension of the disease and inasmuch as many patients suffer repeated attacks of colds, immunizing inoculations are exceedingly practical and of great value. Finding that the nasal discharges contain principally the streptococcus, straphylococcus, pneumococcus, and *Micrococcus catarrhalis*, we give a small dose of mixed vaccine containing these bacteria and repeat the same at intervals of four or five days. This method of treatment produces a speedier convalescence and eliminates drugging almost entirely.

Accessory sinus disease of the nose is too often overlooked as a chronic rhinitis. Untold amount of discomfort and invalidism is thus permitted to continue, whereas immunotherapy can, and generally will, provoke a cure.

Otitis media is a very painful infection, which frequently results in deafness and more serious mastoiditis. The pathogenic organisms found here are streptococci, staphylococci, and pneumococci, and a mixed vaccine of such organisms brings prompt amelioration.

Quinsy sore throat, or peritonsillar abscess, occurs often enough to make a comparison of various forms of treatment. Ordinarily quinsy runs a course of eight or nine days and terminates in a spontaneous opening of the abscess, provided an incision has not been made previously. Recurring quinsies rupture earlier, sometimes on the fifth day. But in each instance the patient becomes severely toxic from the absorption of the infecting matter, and convalescence is correspondingly slow. In your next series of cases use vaccines and then note the milder course and the more speedy recovery of what would prove to be a most painful and distressing ailment.

Young adults suffering from frequently returning spells of tonsillitis are markedly benefited by immunotherapy.

We all have among our patients one or two old people who, annually in the fall of the year, make their appearance with a well-developed bronchitis. This cough, no doubt, furnishes a steady and legitimate income to the physician until the warm and balmy days of spring appear, our patients, in the meantime, having coughed their way through the winter. A series of mixed vaccine inoculations would have added immeasurably to the comfort of these old people.

Pneumonia still exacts its heavy toll of victims and present methods of treatment are, at their best, discouragingly inadequate and unsatisfactory. Immunotherapy opens up a new field of promises and offers a near-specific form of treatment. As in every infection, the speedy establishment of an efficient phagocytosis and the rendering inert of toxic substances is the keynote. What medicine would you care to stake your life on to do this for pneumonia and when a proper suspension of killed pneumococci is injected into one who is ill with pneumonia, a reaction occurs, antibodies are increased which, in turn, make the leucocytes more phagocytic. In our experience vaccines given early in pneumonia have considerably shortened the disease and brought on an early crisis. The most hopeless cases have been tided over into a favorable termination. Mixed stock vaccines have been our chief reliance in our treatment, the temperature and physical signs constituting our only guide in the frequency and dosage of administration.

The pleurisies are treated in like manner. It is needless to say that effusions, when present, should be evacuated.

Typhoid fever is the one disease in which the results of the vaccines can be observed and carefully studied. The usually low and insidious onset, the steady elevation of temperature in the second or third week, and the gradual decline is in striking contrast to the behavior of temperature in pneumonia. One single dose of vaccine administered in pneumonia will drop the temperature from two to three degrees within 12 hours and keep it checked without any untoward symptoms. In typhoid the

temperature falls considerably after an injection, but tends to rise again if the inoculation is not repeated within three or four days. If the typhoid vaccine is administered regularly and systematically, a decided amelioration of all symptoms becomes unquestionably apparent. The anxious facies, the brown tongue, dental sordes, abdominal distention, pain and delirium are missing, and the patients exhibit an appearance of comparative safety. The regaining of strength during convalescence is more rapid. I will quote Forcheimer's Therapeusis: "Regarding the complication of typhoid, such as periostitis, glandular suppurations, cholecystitis, mastoiditis, cystitis due to the bacillus typhosus or secondary infecting organism an autogenous or stock vaccine is the undoubtedly great service."

Acute inflammatory rheumatism has been the bane of the family physician. Pick up any textbook and the first remedies mentioned are the salisylates or coaltar products, and how absolutely inadequate these remedies are we all know. Instead of establishing an immunity they break it down, instead of creating a phagocytosis they disturb it by their intolerant action on the blood cells. Since it has been established that inflammatory rheumatism is an infective process, we must look towards an immunotherapy for relief. The mixed vaccines are daily demonstrating their practical efficiency in this omnipresent disease and it is to be regreted that the profession undertakes the treatment of rheumatism in such a half-hearted way. Rheumatism must be treated aggressively from the onset. Patients should be placed into as favorable condition as possible. The practice of starvation and strict dieting is criminal, every effort should be made to raise their vital resistance to the top notch, and by all means mixed vaccines should be administered, not haphazard, but regularly and, to avoid relapses, over a long period of time. A mixed vaccine containing streptococcus, staphylococcus, pneumococcus, and colon bacillus has been our main standby.

In closing, I will mention one more condition which the general practitioner is frequently called upon to treat and that is septic infections of the extremities following injury. We will take, for instance, the alarming disturbance following a neglected wound or abrasion on the hand with rapid involvement of lymphatic glands in the elbow and axilla. This is a threatening condition, customary poulticing and lotions do not ameliorate but often increase the pathogenic process. By cauterizing the wound with phenol and heading off the bacterial invaders by means of mixed streptococcus and staphylococcus vaccines you are rendering your patient an actual service.

I moderately estimate that I have given almost 15,000 injections within the last twelve years. To be sure, a small amount in comparison with other vaccine practitioners. Fortunately, there have been no untoward results, such as abscess formation, thrombosis, etc., nor any directly attributable fatalities. This has impressed me with their absolute harmlessness. In order not to let my enthusiasm distort my perspective, I abandoned the vaccine form of treatment for several months and treated my patients in true textbook style, and my observations were as follows: As a rule my patients got better, the duration of incapacity for work, however, was prolonged. I was more frequently discharged on that account, also complications were more frequent, such as otitis media, pleurisy with effusions, cardiac complications. Many of my inflammatory rheumatism cases lingered from three to four weeks longer. I had four fatal pneumonia cases in succession. Several otitis media cases were sent to the hospital to undergo operation. Septic infections were decidedly prolonged and were more threatening.

Vaccine therapy, in its own field, does not accomplish everything. Some disappointments are met with. Even the administration of diphtheritic antitoxin under the most favorable circumstances shows up some disappointment. Antitoxin continues to be used nevertheless. In the meantime a mass of evidence is gradually developing, ushering in a new therapeutic era in which the raising of vital resistance, by means of benevolent sensitization, is being accomplished. The employment of vaccines towards this end is not only logical, but practical.

THE MANAGEMENT OF MALIGNANCY BY COMBINED METHODS.

By J. THOMPSON STEVENS, M.D.,

MONTCLAIR, N. J.

STATISTICS show that malignant disease is steadily becoming more common throughout the United States and in other parts of the world. Statistics show also concerning the treatment of this disease with surgery only, with radium only, and with the roentgen rays only, each having its encouraging results, that we have as yet to find a method of treatment whereby a larger percentage of the cases will be cured. The most successful physicians of to-day are coming more and more toward the management of this dread disease through a skillful combination of all the useful methods, and so have increased somewhat the percentage of cures. Of course, by any method of treatment we shall have failures unless some one in the future demonstrates the actual cause of the disease, so that we may enter the contest on an equal footing with the disease, and treat it not only curatively but with prophylaxis. Statistics again show that we, as physicians, can ill afford to depend upon any one method of treatment in all cases, but must use the combined method of surgery, roentgen rays, and radium.

It has been proved that radium is the most powerful form of radiation that we have when applied to a malignant growth. At present, in various parts of the country, cases are being treated either with radium alone, or in combination with the other agents, and in the end we shall have statistics, that will prove beyond doubt, the exact place that this agent should occupy in the management of malignancy. The hopeless cases are being treated in the institutes, many of them with radium alone when better results might be expected if combined with surgery or electrothermic coagulation to remove broken down tissues, and with the roentgen rays for the extensive lymphatic involvement.

When the roentgen rays are indicated we must make sure of our technique, of our apparatus, etc., lest we do no good, or more harm than good. It is indeed painful to note with what crudeness many of the roentgen technicians apply this wonderful agent. They may be excellent men at roentgenography, but being without any knowledge of the physiological action of the rays, and entirely ignorant of the history of malignancy, any good results obtained by them would probably be accidental.

The apparatus must be suitable for the work. There are many good picture machines on the market, but because a machine will turn out excellent roentgenograms we must not assume that it has the capacity for successful roentgenotherapy. In spite of the fact that it is next to impossible for one to do deep work satisfactorily with the ordinary gas tube, it is surprising to note with what frequency the technicians in the smaller towns and cities attempt to administer a dose of the rays with it. In Europe, a good many of the men are still using the gas tube, while we make use of the broad focus, universal type, Coolidge tube. Right here probably lay the reasons for the difference of results obtained in this country and abroad. Usually, we must also have a special tube holder, for it is impossible to get the target of the tube close enough to the skin with the ordinary radiographic stand.

The physician who does roentgen therapy must give his entire time and attention to the work, since a single series will often occupy from six to eight hours, for if it is to be at all successful the treatment must not only reach the affected parts but must be general.

Not many years ago the only recognized successful method of treatment was by surgical removal, regardless of the location or type of the disease. If the growth was inoperable when first diagnosed, nothing was done, or else an operation for relief of symptoms for the time being was done. At present the surgeon realizes that palliative operations are seldom if ever indicated, and that a removal of the growth alone will only hasten its progress. Anti-operative radiotherapy is beginning to be prescribed by the careful surgeon, and nearly all are sending their patients for post-operative radiotherapy.

In the past, the physician or surgeon used to advise the method of treatment with which he was best acquainted, instead of selecting the combined method, or the one that was most sure to give the best final results. There is no question that many cases have been cured by the use of the different methods singly, and many more will be cured by this same method in the future. Each form of radiation has its use in the management of malignancy. We must not only know the indications for the various forms of radiation, but must be in a position to make use of them. Again, radiation should not be used when operation is indicated any more than operation should be done when radiation is indicated. Such a practice soon brings both the radiologist and surgeon into disrepute, since the medical profession is rapidly learning that there is a place and time for each.

Electrothermic coagulation is the method of choice for the removal of broken down necrotic tissue, but the adjacent lymphatics, as well as the diseased area itself, must first receive a thorough course of radiation to prevent the possibility of metastasis. I consider this method of the removal of tissues of prime importance in the prevention of metastasis, as the operation of electro-coagulation seals the lymphatic channels and blood vessels, making the actual removal of the tissues with scissors bloodless. We must keep well within the coagulated area, leaving the remainder to slough off.

The rays given from a Coolidge tube backing up the equivalent of 90,000 volts and filtered through six millimeters of filter material are of practically the same type as the useful gamma rays of radium. There is, however, a difference in the action of the two agents upon both diseased and healthy tissue. And so in spite of the fact that those making use of the roentgen rays alone say that they get the same results without radium, and *vice versa*, show that they have had a limited experience with either method. Time and again Pfahler, and Boggs, and others have proven beyond doubt that the best results will be obtained when radiation is indicated by the use of both methods. However it should be remembered that both roentgen and radium rays are closely related and should be considered together.

To destroy malignant disease with either roentgen or radium rays, it is necessary to get sufficient quantities of the rays to the disease without destroying surrounding healthy tissues, or the tissues through which the rays must pass. When the rays are brought to the disease, a certain quantity of the rays will restrict proliferation, and will gradually produce a necrosis of the growth, while cells farther away may be only stimulated to more rapid growth. There is a definite limit to the quantity of rays that can be safely passed through healthy tissue, without destroying it, and so to surmount these difficulties we must make use of "cross-firing." By this method, we deliver enough of the rays to the disease to destroy it, and only pass through each of the healthy tissues only that quantity of rays which they can safely stand. It has been shown that radiation to a depth of 1½ inches is generally enough to destroy most malignant new growths, but these rays will not produce any appreciable effect upon the surrounding cells in the lymphatics. To produce a deeper effect, we must "crossfire." With a tube of radium or the roentgen bulb eight inches from the skin and passing the rays through from seven to eight ports of entry, a tumor four inches under the surface will receive about the same quantity of the rays as will any one area of skin. Since it is known that healthy tissue is five times more resistant to the destructive action of the rays than is abnormal tissue, it can be easily seen how a destructive quantity of the rays can be delivered to the diseased area without destroying the overlying and surrounding tissues.

I do not believe in the insertion of a radium tube into a cancerous growth unless the surrounding tissues have been efficiently radiated first, so as to more or less completely wall off the diseased from the healthy area. The opening of the growth for the insertion of the radium tube acts the same as an incomplete surgical removal of the disease, i. e., it stimulates the neoplasm to more rapid develop-

ment. And just here lies the main point of difference of radium and the roentgen rays. For localized action radium is generally the better, but for the raying of large areas of the tissues the roentgen rays have first call.

Each tissue of the body reacts in its own way to the rays of either radium or the roentgen bulb. Each tissue has a selective action so to speak. Small doses of the rays act as a stimulant, and if the exposure be long enough and intense enough any tissue of the body can be destroyed. The cells of the disease are first to be destroyed, then the cells of the glands, and the connective tissue last, etc. Then too, there is a difference in the action of the rays on different types of disease; for example, sarcoma of the lymphatics is destroyed by less radiation than is necessary to destroy carcinoma. In sarcoma of the mediastinum roentgen examination reveals a rapid response to either roentgen or radium treatment, while in carcinoma the disease is destroyed with great difficulty, or is only inhibited for the time being. At times there is even a difference in the reaction of the tissues to the rays in different patients, both having the same lesions. It should always be made a rule to give as massive a dose of the rays as the normal tissues will stand in treating either carcinoma or sarcoma. The treatments should also be general. They should cover nearly the entire portion of the body, i.e., if one breast is affected the whole chest should be radiated, front, back, and both sides, always crossfiring onto the disease from each port of entry. It is only in this manner that we can hope to prevent metastasis. Epitheliomata of the rodent type are destroyed by less radiation than is necessary in those of the squamous type. But the fact that the squamous cell epithelioma is so much harder to cure, is no argument against its being radiated. A case of this kind merely throws more strain upon the radiologist and his apparatus. If the case comes to us in the inoperable stage a careful history and study of the physical findings, when coupled with roentgen examination, will show the paths of metastasis, and will have much to do with the success or failure of the radiation treatments. Roentgen and radium treatments are the methods of choice in the management of epitheliomata, since when properly applied, practically all cases are cured and the recurrences are fewer than by any other method. The results obtained by such methods have proved them to be equal or superior to the results obtained by surgery. This is true not only in the early but in the late cases as well. In epithelioma of the lower lip 90 per cent. or more of the cases can be cured, without deformity, while the inoperable cases receive palliation and occasionally one will be cured. It is usually best to use radium locally, both inside and outside the lip, while the roentgen rays can be used to cover front, back, and both sides of the neck to prevent metastasis. When treating epithelioma of the lower lip, we must make sure that we know the paths that the growth is apt to take in the act of spreading through the lymphatics. The two sides of the lip have an anastomosis, and so we must not only ray the side upon which the lesion is found, but both sides. The deep cervicals extend from the mastoid region to the clavicle, some of the lymphatic nodes lying behind the jugular vein and cannot be reached surgically, without first removing the vein. These areas must receive just as careful radiation as the actual ulcer itself if we are to even hope for success. It is a pity to note that in several roentgen laboratories it is the custom to radiate the lesion only.

These cases frequently show an early recurrence in the scar following surgical removal not followed by radiation, and so this is not an entirely satisfactory method. It is no easy matter to reach and remove all the superficial glands, to say nothing of the deeper ones which cannot be reached surgically, and which are probably already infected or soon will be.

Radiation reaches not only the lesion itself but all the glands, both superficial and deep. With a skilful operator the growth and the glands are crossfired upon until they are destroyed. By this method there are fewer recurrences and there is very little scar formation. This is undoubtedly the method of choice, and for once surgery and electrothermic coagulation should be used only for the removal of the actual neurotic area. This operation, however, should not be done until the patient has been thoroughly radiated.

Given a case of epithelioma of the lip, the ideal management would take some such course as is about to be outlined, and by so doing we would stand the best chance of curing the patient forever. The lesion itself, the surrounding areas, the probable lymphatic paths already infected, as well as those to which any possible infection might be carried, in fact, all the lymphatics both sides should be thoroughly radiated. This decreases the vitality of the whole growth, and is more than likely to destroy any metastasis that has already taken place. Then in twenty-four hours the growth is excised or removed by electrothermic coagulation. As soon as the wound is sound, *i.e.* in about ten days' time, we should radiate again and we should push the radiations to the point of utmost tolerance of the skin. The postoperative radiations should be given at about monthly intervals for a year to a year and a half. By this management nearly all cases can be cured forever.

What has just been said about the management of an epithelioma of the lip applies equally well to almost any type of malignant new growth. Any of the technique as well as the order of use of the various methods will have to be altered to suit the case in hand, but more cases can be cured by a skilful combination of surgery, electrothermic coagulation, and radiation than can be cured by any method singly.

The radiation of a growth of the breast does not consist of simply raying the mamma itself, but of raying from the chin to well below the diaphragm at least; front, back, and both sides. always crossfiring toward the disease. We must also go down the arms well past the elbows at times. In fact, the radiations will have to be general at times, if we are to insure our patient against recurrence in some distant part of the body. The axillæ must be crossfired upon, too, likewise the supraclavicular regions, the mediastinum, and the epigastric region.

In carcinoma of the uterus, we must be just as thorough as about the breast, and perhaps more tireless in our technique, for here our rays will be filtered by the thick pelvic bones, in addition to the filtration of the thick soft tissues. Radium justly finds one of its largest fields of application here, but in addition we must cover the abdomen, front, back, and both sides, crossfiring onto the disease and the lymphatics, with the roentgen rays.

In view of the results that have been obtained in the past fifteen years, and which are becoming better all the time, as our technique in applying radiation improves, it seems reasonable to conclude that better results can be obtained in the management of malignancy through friendly co-operation between the surgeon and the radiologist, followed by a combination of surgery, electrothermic coagulation, and radiation, or by the selection of the single method by the surgeon and the radiologist, as the one most likely to give the best results. In the present state of our knowledge let us all, surgeon, physician, and radiologist, insist upon our patients having anti-operative and post-operative radiations so that they may have the maximum protection from this dread disease. Inoperable cases should always be given the advantage of radiation. Some of them can be cured by radiation alone, others can at times be made operable.

A Comparison of Roentgen and Radium Rays for Therapy.

X-Rays.	*Radium.*
1. Technique very exacting.	1. Easy to apply.
2. Rays less penetrating but in greater volume.	2. Rays more penetrating but in less volume.
3. Apparatus large and cumbersome	3. Applicators small.
4. Non-portable.	4. Portable.
5. Danger from high tension.	5. No high tension danger.
6. Large areas can be efficiently treated.	6. Areas much smaller.
7. Costs moderate.	7. Costs high.
8. Deteriorates.	8. No deterioration.
9. Breakdowns frequent.	9. Spontaneous generation.

55 Park Street.

Medicolegal Notes.

Aiding and Abetting Violation of Harrison Act by Issuing Prescription.—A physician duly registered as such with the collector of internal revenue and who had paid the tax was charged with violation of the Harrison Narcotic Law by unlawfully and willfully aiding and abetting certain named druggists in making illegal sales of morphine and cocaine, by giving the persons to whom the sales were alleged to have been made prescriptions, which were by them presented to the druggists and filled by the druggists. The persons to whom the prescriptions were issued were at liberty to have them filled by any druggist selected by them. There was no preconcert between the physician and the druggists charged. It was charged that the defendant contemplated that his prescriptions would be filled by druggists who knew that they were issued to gratify the appetite of addicts for the drugs, and not the alleviation of suffering or the cure of disease. The illegality in the sale was charged to have consisted in the act that the sale was made neither to one who had or was entitled to have an order blank, nor was it made on the prescription of a physician within the meaning of exception (b) of Section 2 of the Harrison Act. That exception is as follows: "To the sale, dispensing or distribution of the aforesaid drugs by a dealer to a consumer under and in pursuance of a written prescription issued by a physician . . . registered under this act." The Circuit Court of Appeals, Fifth Circuit, holds that notwithstanding this exception, a sale by a druggist who knows that the prescription was issued to gratify the holder's appetite, and not to cure disease or alleviate suffering, violates the law, and the physician issuing the prescription, knowing it is to be filled by a druggist having such knowledge, aids and abets the violation. Knowledge by a druggist that a perscription under the act was issued to gratify the holder's appetite, and not to cure disease or alleviate suffering, is essential to guilt, and negligent failure to inquire will not take the place of knowledge. But it was held that an instruction erroneously authorizing a conviction, though the druggist had no actual knowledge that a prescription was wrongfully issued, was not ground for reversal where reasonable men could have drawn but the one inference that the druggist had such actual knowledge.—Doremus v. United States, 262 Fed. 849.

Liability for Injuries Caused by Using Defective X-ray Machine.—In an action for damages for injuries from the use of an *x*-ray machine not equipped with proper appliances, in attempting to secure two *x*-ray pictures of plaintiff's fractured hip, it was alleged that the defendant exposed the plaintiff to the rays 12 or 15 times, more or less, within two weeks, and that plaintiff was given too much of the ray by exposing him for approximately 375 seconds at a target skin distance of about 10 inches, using about 30 milliampères of current, and with a spark gap of not less than 2½ inches, as a direct result of which the plaintiff received severe and lasting burns. It was held that evidence tending to show the use of a machine lacking certain appliances was admissible. There was no pretense that the absence of a filter was, itself, negligence; but, a filter being absent, it was held negligence to make a certain kind of exposures for a certain time without the protection of a filter. Such evidence was necessary for framing an intelligible hypothetical question to an expert. Evidence showing that the sore made by the burn would probably become malignant was held justified under the facts set out in the petition. It appeared that the defendant, having failed after several exposures to procure a picture, induced the salesman who had sold the machine to attempt to take a picture, and upon the salesman's failure resumed his efforts with the same defective machine. It was held that he was not, because of the salesman's effort to take a picture, as a matter of law absolved from liability for the injury caused by the frequency with which the exposures were taken within a given time. The question of whether the defendant was responsible for the effort of the salesman was a question for the jury. The same principle applied to the fact that the defendant, after his first failure, procured another physician to take an exposure with the same machine.—Gross v. Robinson, (Mo.) 218 S. W. 924.

City Does Not Impliedly Warrant Purity of Water Supply.—The New York Appellate Division holds that, where the charter of a municipality provided for the maintenance of a waterworks system, either by general taxation or assessment on the property supplied, the city, though it collected water rates, cannot be deemed engaged in the selling of water, in the ordinary use of the term. Assuming, however, that the municipality is a seller of water, it is held that where it furnished contaminated water and one using it became inoculated with typhoid fever, the municipality is not liable for breach of implied warranty to furnish pure water, in view of the New York Personal Property Law, Section 96, which provides that there is no implied warranty or condition as to quality or fitness for any particular purpose of goods sold, except where the buyer makes known to the seller the particular purpose for which the goods are required, and it appears that the buyer relies on the seller's skill and judgment. The soil through or over which the water passes cannot be minutely examined; contamination of the water can be restricted, but not prevented; inspection alone will not reveal the presence of bacteria; analyses of the great volume of moving water collected in the ponds for distribution cannot be made; and an inspection, an examination, or an analysis of every drop of water furnished is beyond the power of the seller.—Canavan v. City of Mechanicsville. 180 N. Y. Supp. 62.

THE PROGNOSIS OF ERYSIPELAS IN THE AGED.

ERYSIPELAS has the reputation of being very serious at the two extremes of life. Decorse examined the case histories of 3,072 patients with erysipelas and found a mortality of 5.37 per cent., and he concludes that in the aged or in debilitated subjects in adult life the prognosis is almost always fatal. More recently, Lucien and Parisot have given 18 per cent. as the mortality in fifty cases in subjects between sixty and eighty years of age. The death-rate at other ages given by these observers is 4.7 per cent. from 0 to 20 years; 7.2 per cent. from 20 to 40, and 6 per cent. from 40 to 60 years. Lamy's statistics of cases occurring between 60 and 87 years gives a lower mortality. There was only one death in thirty cases, otherwise 3.30 per cent. which is a lower death-rate than in youth and adult life, and Lamy inclines to the belief that extreme age in no way aggravates the prognosis. In elderly subjects erysipelas does not find a soil favorable for its virulence, and the attenuated forms of the process described by Juhel-Rénoy and Bolognesi—so common in old people—never have a bad prognosis. When death occurs in streptococcal dermatitis in elderly subjects a blood examination might indicate a bad prognosis if it contained the streptococcus, since Achalme maintains that the presence of this bacterium in the general circulation is a proof of severe infection, but this fact does not necessarily imply a fatal issue as has been erroneously supposed. Visceral morbid stigmata in old people, such as diabetes, renal, hepatic, and cardiac affections, are badly influenced by erysipelas so that in them the prognosis is bad. Juhel-Rénoy and Bolognesi think that the state of the kidneys is an important factor in the prognosis and even the symptomatology of erysipelas, but Lamy has observed cases of old people with chronic nephritis in whom erysipelas ran a mild course.

In his thirty cases of erysipelas in old people Lamy states that all had manifest arteriosclerosis, some with very high blood-pressure and an intense accentuation of the second aortic sound. Almost all had bronchitis; one with chronic nephritis and cardiac hypertrophy was a tabetic in the paralytic phase and this was the only fatal case. Of the remaining twenty-nine who recovered, seven had renal lesions and three of the latter offered evidences of mild hepatic lesions. The recovery of these patients cannot be regarded as contradicting the opinion of other observers because Lamy says that they had moderate renal and hepatic symptoms such as are present in the usual semeiology of senile pathology, but he nevertheless believes that the pessimism of most text-book writers concerning preexisting visceral lesions in erysipelas cases are exaggerated and susceptible to the physician in his prognosis in cases of erysipelas in the aged. Finally, the prognostic gravity of preexisting cardiac lesions mislead, whether mitral or aortic insufficiency or disturbances of the contraction of the myocardium, seems doubtful. It is difficult to admit with Lucien and Parisot that every perfectly compensated latent cardiac process should make the prognosis gloomy in ordinary erysipelas in old subjects. It is known that the heart shows only a mild intolerance to the infectious lesions of streptococcal dermatitis and Teissier has recently studied the frequently mild manifestations of this disease on the pericardium and myocardium.

As in the adult, so in the aged the prognosis of streptococcal dermatitis is poor in cases of advanced phthisis, lead, morphine, or alcoholic intoxications, likewise when the erysipelas is associated with typhoid fever or other infectious disease. It should be recalled that the prognosis of preexisting diseases to which an erysipelas becomes added has been the subject of numerous discussions and in many of them the skin process has had a salutary effect. From the viewpoint of local affections streptococcal dermatitis superadded to a varicose ulcer results favorably, since Roger records six recoveries from the ulcer out of seven cases he observed. Lamy met with one case in which the ulcer was made rather worse by the erysipelas.

As to the prognosis of preexisting general affections, Roger believes that cardiac, hepatic, and renal lesions—the most common in elderly subjects—are not aggravated by erysipelas, while the torpid form of phthisis, so common in old age, does not benefit by this disease. It has been affirmed that tuberculosis, influenza, and measles subside after an erysipelas, but pulmonary tuberculosis is known to undergo a new and fatal evolution after erysipelas.

The general prognosis of senile erysipelas should be regarded as favorable and is not distinctly darkened by moderate renal or myocarditic processes, compensated valvular lesions, or hepatic disorder.

DIETETICS IN DEFICIENCY DISEASES.

MOURIQUAND considers in the *Journal de médecine et de chirurgie pratiques for* September 10, 1920, xci, 17, the increase in our knowledge from a study of the dietetics of deficiency diseases and our new acquisitions in alimentary biochemistry. In collaboration with Professor Weill he has done much original work in this field. The conception of deficiency diseases must first be illuminated. The ideas of ordinary inanition and of autointoxication

are quite foreign to the subject, and lack of balance or monotony of diet is a separate subject. The real deficiency is in substances of the nature of enzymes or catalysts, and unlike calories, these units do not require to be present in quantities but only in quality. The vitamines may be shown to be living substances, although the word "living" may be used more or less figuratively. Thus the juice of a freshly picked lemon may be imagined as containing some unknown substance in a state of life which is forfeited after a certain period and which is destroyed by cooking, preserving, etc. This unknown substance present in fruits is able to persist after the latter are plucked and for an indefinite period. It seems only necessary that the fruit retains its juices. Ordinary sterilization and the decortication of cereal grains cause the loss of the vitamine content of the dried grains, and it is evident that the vitamines in the latter, which may be preserved indefinitely, must differ from the vitamines in fresh fruit juices. This is also evident from their activities in the body, for the deficiency diseases corrected by the fresh juices are known as scurvies, while the related affections due to sacrifice of the cortex of grains are expressed chiefly as polyneuritis. Conditions not yet shown to belong to the avitaminoses are pellagra and rachitis. Other vitamines are believed to preside over ordinary growth, so that there must be some cooperation between vitamines and hormones. The question of identity was at one time broached, but at the present moment it has been apparently demonstrated that certain aminoacids in minute quantities (lysin, tryptophane) are indispensable for growth or equilibrium of development. Certain minerals, as manganese salts, have also been regarded as catalysts in promoting the utilization of proteid foods, so that the hormones of the thyroid, hypophysis and other endocrine glands may not be able unaided to preside over growth and development. No mention is made of cholesterol and other lipoids in this connection.

If a human subject is fed on food poor in vitamines the first consequence is indigestion, although the food may be of the most bland and easily digested type. These disorders comprise loss of appetite, intestinal disturbances, chiefly diarrhea (the diet is ordinarily favorable rather to constipation), and pallor. These threshold symptoms, like the fully developed deficiency diseases, respond quickly to the vitamine regimen—meats, butter, legumes, and fresh fruits. Where beriberi is endemic the nursling may be benefited by proper feeding of the mother or nurse. In artificial feeding it is possible to avoid deficiency disease by using fresh milk only, avoiding both sterilization and conservation of the fluid. There is a danger attached to weaning, for the solid food given the child may be lacking in vitamines and the same danger is present in theory during the entire period of growth and development. The adult does not require growth vitamines but does still demand those which preside over equilibrium. Dyspepsia, anorexia, and diarrhea should cause an investigation of the diet for vitamine deficiency.

THE ACIDOSIS SYNDROME.

LABBÉ gives a sort of synthetic review of the general subject of acidosis in the *Journal de médecine et de chirurgie pratiques* for September 10, 1920, xci, 17. The term was first introduced by Naunyn in connection with the presence of oxybutyric acid in diabetic coma. Levy extended the meaning to include any condition characterized by insufficiency of bases and excess of acid in the economy. Of conditions affiliated with diabetic acidosis are cyclic vomiting with acetonemia, so-called dyspeptic coma, diaceturia in certain cases of incoercible vomiting of pregnancy and other expressions of gestational autotoxemia, these being associated with hepatic insufficiency. The acidosis of inanition from whatever source belongs in the same category. All forms are characterized by the presence in the urine of oxybutyric and diacetic acids and acetone. Recently shock has been ascribed in part to acidosis. Any condition which benefits by intravenous or subcutaneous infusion of sodium bicarbonate solution may be an acidosis. From this viewpoint surprising therapeutic effects have sometimes been obtained.

The author is especially interested in the form which proceeds from hepatic insufficiency. One patient with abscess of the liver showed glycosuria and diaceturia and died in coma. Others also exhibited delirium with coma and after death lesions of the liver were found. But not always do we find lesions in the liver when they should be present, and so we must postulate the existence of a functional insufficiency of the liver. Acidosis is not seen at all in acute infectious diseases and is usually absent in digestive and hepatic diseases, but is not uncommon in visceral inflammations such as appendicitis and salpingitis. To a certain extent it is an index of the severity of appendicitis and is therefore absent in the milder cases. It is still more common in cholecystitis and pericholecystitis. In hepatic colic it may be intense.

These types are probably due to the fact that the liver is closely related through the portal circulation with the gall ducts and bladder and the appendix. The acidosis element in chloroform and ether death has a similar motivation. In all of these affections there is an inhibition of the hepatic functions.

Acidosis is an anomaly of metabolism due, in the author's opinion, to hepatic insufficiency. He has found the acetone bodies in these cases associated with aminoaciduria and urobilinuria, which have the same significance. The acetone bodies are largely derived from the fats but also in part from protein. The author distinguishes between latent, somnolent or comatose, deliriant, dyspneic, and gastric forms in which vomiting is a marked symptom. Diagnosis is made essentially through the urine although the acetone bodies therein found may not be associated with symptoms (latent forms). Generally speaking, the prognosis is serious although many cases are benign. Treatment comprises feeding, which has to be done chiefly with carbohydrates, the use of alkalies, hepatic stimulants, and in theory hepatic extracts.

THE PHYSICIAN'S ROLE IN THE TREATMENT OF RECTAL CANCER.

THE authors below mentioned refer not to any exclusive medical management of cancer in this locality but to the rôle of the physician in dealing with the patient who consults him. According to Bensaude, who writes the article in association with Ernst (*Journal de médecine et de chirurgie pratiques*, September 25, 1920, xci, 18) it is usually the physician who first sees the patient. In connection with digital and rectoscopic examination in routine work he comes at times on rectal cancer when it is low placed, but if the location is high he will be very likely to overlook it. If he finds a suspicious growth he should know the conditions of operability and if operation is refused he should at once recommend a radium expert and keep the case under observation during treatment. The formation of an artificial anus should also be thought of in certain cases and the medical man may be of use in overcoming the repugnance of the average patient to this step, as well to extirpation itself. The anus may be either temporary or permanent. The physician should know the contraindications to radical operations, such as cachexia, metastases, extension of the process into nearby organs, advanced age, etc. Colloid cancer in relatively young subjects is practically certain to relapse fatally and may be regarded as inoperable. In all such cases an iliac anus is the only resource. Operable cases may have the additional benefit of radium, as may cases on the border line.

The major questions of operation, such as the route, the amount of tissue to come out, etc., are strictly within the province of the surgeon. In France the sacral operation has been discarded chiefly in favor of the abdominosacral in two stages. The mortality here is very high and if we include the recurrences a patient has a little less than an even chance. Certain figures from other countries seem much better than these, which may be due to selection of cases and hold good for small personal series, but we can only take the general results as we find them. In all radical interventions the artificial anus is a necessary preliminary step which eliminates the inflammatory complications and leaves a simple cancer for removal. The medical man can assist nature by appropriate treatment after the establishment of this anus and in two or three months' time the degree of improvement is often remarkable. The cancer is presumably increasing its boundaries, but left to itself its growth rate is naturally slow—sometimes lasting several years before the final issue. The artificial anus requires the daily supervision of the medical man, and the authors enumerate many useful details of management.

It is the supervision of the artificial anus which is indicated under such a variety of circumstances that makes rectal cancer peculiarly a medical disease for the family practitioner. This does not happen in other forms of cancer. Suitable diet plays a major rôle in the management of artificial anus, and this is even more true of cases in which no anus has been established, for the necessary opiates produce constipation which must be antagonized by giving laxative foods.

THE MALE HOMOSEXUAL AS A SOCIAL PERIL.

THE quasi-humanitarian attitude of medical jurists like Hirschfeld towards homosexuals finds no echo in the pages of a monograph by Fried of Vienna, reviewed in the *Schweizerische medizinishe Wochenschrift* for July 29, 1920, i, 31. This author insists that homosexuality is none of the things claimed in its extenuation. It is not a neurosis nor is it amenable to psychoanalysis or any other method of treating neuroses; it is not due, as Hirshfeld alleges, to an irresistible impulse; there is no question of diminished responsibility. There are indeed severe defects of character—spite, opportunism, absence of honor, cowardice, joy in injury to others. Fried repudiates the teaching that geniuses and great artists have homosexual inclinations. There is a fundamental tendency to form cliques and it is through this tendency that the homosexuals are a social menace. A prominent member will surround himself with underlings of his own type. It was an Austrian commander with his homosexual satellites who sold out the garrison of an important town to the Russians. The police will never move against a rich homosexual. On the other hand, the female homosexual is not a social menace, evidently because she does not associate herself with her kind on a large scale. Normally sexual men often pervert themselves for gain. The reviewer of the book approves of much of its teachings, and a reaction against the doctrine of irresponsibility of the male homosexual which takes him from the jurisdiction of the ordinary police magistrate is bound to come, and the pendulum is bound to swing back to the natural attitude of the public against this class of offenders.

BILHARZIOSIS IN THE NEAR EAST AND MEDITERRANEAN SOUTH SHORE.

THIS affection, according to Abbatucci writing in the *Bulletin Médical* for July 17, 1920, xxxiv, 36, now prevails in practically all of the colonial possessions of the French—Madagascar, Martinique, Guadaloupe, and especially Africa, and there not only in the Northern possessions but in Guinea. It follows the Mediterranean south shore from Morocco to Syria. The question must arise why the immunity of France? The host is a fresh water mollusk and Roubaud has examined various congeners of this creature in the regions of Paris for evidence of the bilharzia with negative results, although there have been in Paris various colonials with the disease. The parasite in any case is probably unable to find a host in the waters of the temperate zone. Ordinarily only urine containing the parasite, certain gastropods for hosts, and methods for contaminating the water supply are needed to develop the disease. It has been shown beyond doubt that bathing in infected water will lead to infection. Washing in the water of certain wells also suffices and all collections of fresh water, whether wells, cisterns, or open ponds, etc., contain the mollusks in question. The most

important country at present from this viewpoint of the spread of the disease is Syria, including Palestine, where French troops have recently been stationed. Until recently we have had no therapeutics for bilharziosis, but now good results are attainable from the use of emetine according to a special technique of injection introduced by the English army surgeons.

Arsenic in Parkinson's Disease.

Many years ago Erb reported unfavorably on the use of inorganic arsenic in this malady. In 1899, however, Gautier introduced the cacodylates into medicine and recommended them especially in the same. It was extensively tested and in a small minority of cases seemed to give results. Dr. Carlotta Porru, assistant to Professor Rossi in the University of Sassari, publishes the experience with this resource in *Il Policlinico*, Sept. 6, 1920, xxvii, 36. In 1911 the then new organic arsenical salvarsan was tried out in an especially rigid case of paralysis agitans without evidence of syphilis and the result was apparently *nil*. The idea then slumbered until the report in 1919 by Lhermitte and Quesnel in praise of sodium cacodylate, the action of which was said to have been brilliant. The technique was new and consisted in incorporating as much as 2.5 gm. in a day at intervals of several days, with a minimum of half a gram. The treatment was at once tested at the Sassari clinic. One woman received 13 grams of cacodylate in ten days with but slight relaxation of the rigidity. It was an extreme case of twenty years' duration. Three patients whose malady had lasted ten years were next treated. One received 14 grams in twenty-five days, another but 4 in twenty-two days, and the third 13 in twenty days. The injections appear to have been made daily without periods of intermission. There were no instances of intolerance to arsenic and there was a certain amount of general improvement, but without the disappearance of any of the characteristic symptoms. In a third group of three individuals whose malady had lasted about six years, the dosage was slowly elevated until the patient received 15 grams in fourteen days. One of the three was decidedly benefited in all respects while the other two were uninfluenced. The remedy then holds out a little hope in cases of relatively brief duration. The method is being tested in spastic paralysis as well.

Rasmussen's Aneurysm.

Letulle reports 5 cases of this affection in the *Bulletins et Memoires de la Société Anatomique de Paris* for June, 1920, xvii, 6. The affection thus described is a tuberculous aneurysm of the pulmonary artery. A student, Tétard, will write his graduation thesis around these cases and in view of the approach of this event great pains have been taken with the histological studies. The first 4 cases were classical and in agreement throughout with Rasmussen's description—small, whitish pockets in part effaced, projecting into pulmonary cavities and formed at the expense of branches of the pulmonary artery of considerable importance. Each of these minimal parietal aneurysms is empty and fissured, being thus without the clots seen in syphilitic arterial aneurysms. The fifth and atypical case was of notable size, spheroidal, resembling a small and partly healed cavity. Technically it was a Rasmussen aneurysm cured by thromboarteritis obliterans. In the four typical cases the walls were calcified; rupture had caused death by pulmonary hemorrhage. The portion of the artery which projected into the cavity was in close contact with caseous matter. The aneurysmal pocket had undergone tuberculization and had been infected from the caseous focus just mentioned, but the mechanism is obscure; for how could bacilli cause a panarteritis such as undoubtedly occurs? The inflammation is succeeded by ulceration and aneurysmal dilatation aided by the pressure of the blood. Study of analogous syphilitic aneurysms, however, appears to show that the mechanism must be identical in the two affections. It appears that a vascular reaction occurs in the affected arterial segment which becomes transformed into fibrovascular tissue and this in turn undergoes caseation. The wall is rapidly disorganized and dilates. Along with caseation we see vitrification and hyaline degeneration which in animal experiment can be made to develop with great rapidity.

News of the Week.

Russian Food Situation Serious.—Press reports announce that Soviet Russia has never experienced such a food crisis as exists at present. Moscow and other cities are said to be paralyzed by famine. The Red Army, too, is in dire need of food.

Drug Addiction Increasing in France.—Opium smoking and the use of cocaine and morphine are said to have increased enormously of late in France. A regular traffic in drugs is carried on in the less reputable cafés. Much of the "dope" is smuggled through from Germany.

American Supplies for Jews of Soviet Russia.—The first large shipment of relief supplies for the Jews of Soviet Russia was started recently from the Baltic port of Reval, Esthonia, for Moscow. The supplies were purchased with $500,000 appropriated by the Joint Distribution Committee of the American Fund for Jewish War Sufferers. Distribution will be under the direction of the Moscow committee of Jews, with the cooperation of Dr. Frank Rosenblatt of New York, who represents the committee in Moscow.

Danger of Typhus Not Abating in Poland.—Colonel Harry L. Gilchrist, commander of the American Polish Relief Expedition which has been working more than a year, in conjunction with the Polish Government, in an effort to control the typhus situation, considers the danger greater than ever. The Bolshevist activities in August, when the fate of Warsaw was hanging in the balance, augmented the danger of the spread of the disease, for the following reasons, according to Colonel Gilchrist: Complete abandonment of all typhus fever work in the worst typhus fever districts of Poland; capture by the Bolsheviki of all Eastern quarantine stations and removal of the barriers established under great difficulties; capture and destruction of much of the paraphernalia and materials which had been distributed in many towns and villages

throughout the typhus districts; in reduction by Bolshevist troops of a new source of contamination to places free from the disease, and the infecting of the armies of Poland and infecting of the populace returning to homes recently occupied by Bolshevist soldiers. It is predicted by the most conservative that the number of new typhus carriers scattered over all Poland will reach many thousands, and the financial loss due to the destruction of sanitary materials, crops and other property will run into millions of dollars.

"The-All-Year-Round Suit."—According to press reports, London doctors are waking up to the fact that the majority of people wear too much clothing, particularly wool and fur. If paper clothing could be made "silent" and untearable, they claim, it would be more hygienic and effective than woolen or cotton clothes. An all-the-year-round suit is advocated as a hygienic measure.

Pine Coffins in Switzerland.—The Department of Commerce has received advices from American consuls in Switzerland to the effect that the cantons generally provide free burial for everyone, pine coffins, stained outside and unstained within, being provided. Coffins of material other than pine are prohibited by law. A veneered pine coffin, decorated as desired, may be purchased provided nothing is used which will tend to delay decay of the coffin and the body within.

One Bath a Week for the Viennese.—Report comes to the effect that Saturday is official bathing day in Vienna. The scarcity of coal makes hot water a luxury, and since cold water bathing seems to be practically tabooed by the Viennese, it has been made a misdemeanor to waste hot water, the natural corollary being an official decree limiting the number of baths. A farther stroke of economy limited the bathing time to one day, Saturday being selected. Signs in hotels read: "It is officially decreed that only on Saturday may baths be taken."

High Infant Mortality.—The infant mortality rate is higher in Akron, Ohio, than in the majority of Ohio cities and one of the highest rates in the country. The rate of infant mortality in Akron is 114 for every 1,000 babies born. The congested conditions arising through inadequate housing facilities are blamed for the abnormally high rate of infant mortality.

Public Health Service Takes Over Army Hospitals.—The O'Reilly Hospital, Oteen, N. C., eight miles from Asheville, has been taken over by the Public Health Service, and will be continued as a tuberculosis hospital with about one thousand beds. Hoff General Hospital at Fox Hills, Staten Island, will be continued by the Public Health Service as a general hospital with a capacity of about five hundred beds.

Nurses Needed.—The United States Public Health Service announces the need of hundreds of graduate nurses for its general hospital work and particularly for the care of former soldiers suffering from nervous and mental disorders. The Public Health Service accordingly purposes to establish a training school for nursing in neuro-psychiatric diseases in its special hospital (No. 49) on Grays Ferry Road, near Philadelphia, where nurses with general training may take a special course in this class of work. This hospital has a capacity of 240 patients and will afford exceptional opportunities for instruction in the most modern treatment. The hospitals now operated by the U. S. Public Health Service are already 150 nurses short; and the Service faces the necessity of opening several new ones with an inadequate force. Applications should be made to the Surgeon General, U. S. Public Health Service, Washington, D. C.

Anesthetists Needed.—The United States Civil Service Commission announces an open competitive examination for anesthetist, to fill a vacancy in Freedmen's Hospital, Washington, D. C., and vacancies in positions requiring similar qualifications. Salary, $1,200 a year, plus the $20 a month increase granted by Congress, with board. Applicants should apply for Form 1312, stating the title of the examination desired, to the Civil Service Commission, Washington, D. C., or to the Secretary of the local United States Civil Service Board. Receipt of applications closes December 7, 1920.

Radium Thrown Away.—A woman patient in Faxton Hospital, Utica, N. Y., was being treated for cancer of the breast, a milligram of radium, valued at $13,000, being used. Because it irritated her, so the story goes, she went to the bathroom, took off the bandage, and threw the radium away, being ignorant of its value. Workmen were immediately put to digging up the sewers in the vicinity of the hospital, in the effort to locate the metal.

Red Cross Drive Begun.—Armistice Day, November 11, marked the beginning of the Red Cross drive. Five thousand men and women in New York City will conduct the two weeks' canvass. The New York Chapter expects to reach the goal of $400,000.

Anti-Litter Campaign.—The Merchants' Association of New York City, through its Anti-Litter Bureau, has enlisted the cooperation of the Boy and Girl Scout organizations in the work of keeping the streets of New York City free from litter and in educating the public to maintain these conditions.

Columbus Hospital.—The Missionary Sisters of the Sacred Heart, who have conducted Columbus Hospital in East Twentieth Street since it was founded in 1892, have recently taken over St. Lawrence Hospital in East One Hundred and Sixty-third Street, and the old institution will be moved to the uptown quarters. In the near future the hospital will be enlarged by the erection of a modern ten story building on a vacant lot adjoining the St. Lawrence Hospital site.

Gifts to Fifth Avenue Hospital.—The opening of the two weeks' drive to raise a $2,000,000 building fund for the new Fifth Avenue Hospital was marked by gifts aggregating $485,000, contributed as follows: Corn Exchange Bank, $30,000; J. H. Emery, $30,000; Fifth Avenue Bank, $30,000; Mrs. George J. Jackson, $30,000; Mrs. R. L. Sweet, $35,000; T. F. Manville and H. E. Manville, $300,000. This new institution is intended by those constituting the Fifth Avenue Hospital Committee, to take the place of the Hahnemann Hospital and the Laura Franklin Free Hospital for Children.

Hahnemann Hospital Association.—Homeopathic physicians and laymen interested in the perpetuation of Hahnemann Hospital (which it is proposed to replace by the new Fifth Avenue Hospital) as set forth in the charter have organized the Hahnemann Hospital Association, with offices at 145 West Forty-

third Street. George A. Gangloff is Acting Secretary.

Bronx Maternity Hospital Opened.—With a capacity of forty beds, the Bronx Maternity Hospital has been formally opened for the reception of patients.

Obituary Notes.—DR. THEODORE G. WRIGHT of New York City died Nov. 1, at the age of eighty-seven. He was graduated from New York University Medical College in 1865. He was a member of the Connecticut State Medical Society.

DR. L. J. DENCHFIELD of New York City died suddenly Nov. 4. He was graduated from the Medico-Chirurgical College of Philadelphia in 1899.

DR. CHRISTIAN OSWALD JOERG, for thirty years a practising physician in Brooklyn, N. Y., died Nov. 4, at the age of seventy-seven. Dr. Joerg was born in Leipzig, Germany, and was graduated from the University of Leipzig in 1870, specializing in gynecology. He came to this country in 1881. He was a fellow of the American Medical Association.

Obituary.

SAMUEL J. MELTZER, M. D.

NEW YORK.

Dr. Samuel J. Meltzer, distinguished physiologist, died of heart disease Nov. 7. He was born in Russia in 1851, received his general education in Königsberg, Prussia, was graduated in medicine from the University of Berlin in 1882, came to this country the following year, and entered the practice of medicine in this city.

In 1906 Dr. Meltzer became Director of the Department of Physiology and Pharmacology at the Rockefeller Institute for Medical Research, in which capacity he served to the time of his death. In the course of the research work which he conducted at the Rockefeller Institute he made many important observations, among them being his well-known findings concerning resuscitation, pharyngeal insufflation, peripheral mechanism, and tetanus. He was one of the founders and first president of the American Association for Thoracic Surgery, organized in 1918.

During the World War Dr. Meltzer served as major in the Medical Reserve Corps of the United States Army. Among the societies to which he belonged may be mentioned the American Medical Association, the American Association of Anesthetists, the Association of American Physicians, the American Gastro-enterological Association, the American Asssociation of Pathology and Bacteriology, the New York Pathological Society, and the American Society for Experimental Pathology.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, Oct. 15, 1920.

The Opening of the Session of the Medical Schools.—In a former letter two or three of the addresses given at the opening of the London medical schools were referred to at length, but no mention was made of the fact that generally speaking this time honored custom has almost fallen into desuetude. Up to the end of the year 1800 most of the great medical schools made a distinct feature of the opening address on October 1. In the metropolis these introductory addresses were delivered as a rule by distinguished members of the staff who undertook the duty in rotation and who discoursed on the nobility of the career the student had chosen, emphasizing the point that he would have to work hard only to find probably that his labor was inadequately rewarded, finally impressing upon him that he had done well to join this school on account of the eminent attainments of the scientific leaders who had joined the staff. At the present time orations of this nature are obsolete. The opening address with its obvious truisms is either abandoned or a well known man not connected with the institution is asked to speak, his theme being medicine or sociology, in whichever subject he had made his name. This is evidence of the new spirit of the medical schools, and shows that the universality of medicine is now fully recognized. One of the most striking addresses was given by Professor Swale Vincent, Professor of Physiology, University of London, at the opening of the session at the Middlesex Hospital Medical School. He dwelt upon the various problems with which medical research and education are concerned and ventured to prophesy that in the evolution of the British medical curriculum there would be a general if not universal adoption of the arrangement which had been found most advantageous in the universities of Europe and America. Professor Swale Vincent pointed out that perhaps the greatest hindrance to progress in medical education in Great Britain had always been, and still continued to be, the difficulty in finding money to defray the expense of buildings and laboratory equipment, to say nothing of the salaries of teachers. He urged that the Government should support the universities rather than separate research institutions, which they were now accustomed to do. He said that the reason for the deplorable condition of the British universities from the scientific standpoint was clearly to be sought in the lack of interest in and appreciation of scientific work on the part of the general public and the reflection of this state of affairs in the attitude of the British Government. In regard to medical education, the public had never realized that efficient training of doctors was absolutely dependent upon a sound scientific education. This was, of course, only an expression of the British suspicion and scepticism as to the value of science. There had been a partial awakening, but the poverty-stricken universities still stood as a sign that everything had yet to be done. State support to the universities should be generous and complete. Mr. Richardson Cross gave the inaugural address at King's College Hospital and the address was prepared especially for the students and dealt with the development of the modern doctor. He sketched the personal characteristics and skill of the men on the staff of King's College Hospital 35 years ago when Lister's methods had not been introduced, or were only commencing to be introduced, and when the the most skilful

surgery was frequently rendered useless by the blood poisoning that followed operation. At that time, the mortality after amputation on operations of a similar grave character was not lower than 25 per cent. and even reached 40 per cent. Mr. Cross went on to describe the revolution in surgical methods which followed the work of Lister, who joined the staff of King College Hospital in 1877. Dr. Gossage in the opening address at Westminster Hospital drew attention to the tremendous increase in the number and the complexity of the subjects which the medical student had now to be taught compared to what was the case when he was a student. However, it was with the teachers that Dr. Gossage was more concerned than with the students. Teaching was the least well paid of all the professions, and, as in other branches of secondary and technical education students' fees were completely inadequate even to supply the necessary apparatus, much less to pay a salary commensurate with their labor to the teachers. In the past professional men taught their future colleagues in their spare time while they earned their livelihood by the practice of their profession, and were repaid because the successful teacher obtained the largest professional reward. To some extent, in the more purely professional subjects of medicine, surgery, and midwifery this still held, and it was a great advantage to the student to be taught by active practitioners. Other subjects of the curriculum, such as pathology, were now demanding the whole of the teachers' energy, leaving him no time for practice and even if there were time, eminence in these sciences did not lead to remunerative professional work. There was, too, a tendency both here and in other countries to demand that a major part of the teaching in even medicine, surgery and midwifery should be done by wholetime teachers and assistants. In America and to some extent in England the difficulty was partly met by the munificence of private individuals, who had endowed universities and schools for medical education; on the continent of Europe the financial responsibility was undertaken by the Government. London, the largest British center for medical education, had never received much assistance from endowment, and in these days when it was becoming impossible to raise from the charitable even sufficient money for the hospital treatment of the sick, further endowment of education became excessively unlikely. As the *Lancet*, Oct. 9, last, in an annotation on the subject pointed out, it was to the Government that the schools must turn for adequate provision so that in material and personnel the schools should be equal to the best. Before undertaking any such responsibility the Government must be expected to insist on economy of management, and it might be expected that it would insist on a reduction in the number of competing schools and hospitals, which might be considerably reduced by amalgamation. The proper use of London's unrivalled opportunities was also likely to be demanded, so that the teaching possibilities of the numerous special hospitals and infirmaries should be utilized, and a further multiplication of unnecessary institutions to the detriment of those already existing prevented.

Hospital Dinners.—Although St. Bartholomew's Hospital was one of those which has discarded addresses the annual hospital dinner was held after a lapse of seven years due to the war. It was found that the Great Hall of the hospital would not seat all those who wished to be present and so the offer of the Lord Mayor of London to place the City Guildhall at the disposal of the hospital was accepted. The dinner took place there on the evening of Oct. 1, last. Sir Anthony Bowlby, President of the Royal College of Surgeons, occupied the chair. Among other distinguished members of the medical profession present were Sir Norman Moore, President of the Royal College of Physicians, who proposed the toast of the evening, "The Hospital and School"; Sir Clifford Allbutt, Regius Professor of Physic at the University of Cambridge, and Sir Archibald Garrod, Regius Professor of Medicine at the University of Oxford, who is a member of the staff of the hospital and until recently head of the hospital medical unit. At a luncheon held on Oct. 1, last, to inaugurate the appeal for funds to establish a department of industrial medicine at St. Mary's Hospital, Sir Almroth Wright, director of its pathological institute, said that in medicine practice is always outrunning knowledge and at present this must be so. Advice was given to patients to the best of the doctor's ability, but the doctor himself knew only too well that he was not always competent to give it. He therefore considered that a hospital ought to have two staffs, one to apply the knowledge already available, and the other a research staff. At St. Mary's Hospital the directors of departments of the Pathological Institute were now recognized as members of the staff of the hospital. He laid stress upon the importance of having both staffs attached to a hospital instead of segregating research work in separate institutions. One advantage was the ease with which the research worker could obtain material selected and sent on to him by the clinician. Sir Almroth Wright then discussed the subject of industrial medicine. In the Crimean War ten men died from disease for everyone who died from an injury; this disease mortality in war had been prevented only by medical concentration on the "soldiering" industry and equally marvelous results would be obtained if the same attention were given to conditions of life work and ill-health in all industries.

Women in Medicine.—An endeavor is to be made to obtain funds for the purpose of extending the Royal Free Hospital, London, School of Medicine for Women. This is the only school of medicine in Great Britain solely for women, although some of the other London schools have opened their doors, and others are thinking of doing so to female medical students. The jubilee of this school is approaching, and the committee appointed to launch a campaign for funds are very anxious that the event should be celebrated in a fitting manner. The great work which the school has done and the promising future which lies before its students was discussed recently by a high authority in an interview given to a representative of the *Observer*, the foremost London Sunday journal and published in that journal of Oct. 10, last. The School of Medicine for Women according to this authority

has been a pioneer in university education. Through its work women have taken good places in medicine and surgery, in physiology, chemistry, radiography and research, and have helped largely in opening responsible posts in all branches of work. The special need at the moment is to place the medical education of women on a wider and firmer basis. Five years ago the school was enlarged for an annual entry of seventy-five students. Already it has far outgrown that number, the average entry being about 105. In the same way the school has outgrown the hospital. However, the need for more funds comes at a happy juncture, because, whilst the hospital receives as, hitherto, free of all charge poor patients who are unable to contribute anything towards their maintenance, numerous patients, men, women and children, seek admission who can pay the cost of their maintenance. If only, therefore, more wards can be built there will be no extra charge on the revenue of the hospital. The question is often asked why the authorities should try to extend this school when some of the men's medical schools in London now take women students. These schools only began to take them during the war, and the number is in many cases limited to 5 or 10 per cent. It is strongly felt by the authorities of the women's school, that though the co-education of men and women students has been carried on for many years in the newer universities, yet the hospitals and infirmaries connected with these schools have hitherto withheld posts of responsibility from women graduates, and it therefore seems best to have a strong school for women students only, until all medical schools, together with all hospital appointments are open to men and women on equal terms. As to the future that lies before medical women, at present, and so far as can be judged, there are plenty of openings both in public services and in private practice, at home and abroad for qualified medical women. The large number of women desiring to enter as medical students has proved quite embarrassing to those London medical schools which have thrown their doors open to them. The rush of men students is greater than ever known and there are also the ex-service men to be considered. These will be received at considerably reduced fees. There is not only lack of accommodation at most of the hospitals but the financial state of affairs enforces great economy. The situation is also delicate in more than one respect. The woman student demands to be placed on an equality with the man and to be given her due share of hospital appointments. Thus the authorities of the hospitals to which she is allowed to enter are placed somewhat on the horns of a dilemma. It seems that if the female student has shown herself fitted to hold appointments it will be unfair to deny her. The apportionment of such appointments in equitable proportion is in itself a matter requiring a good deal of diplomacy. Moreover, while some women may have proved themselves equal to any medical or surgical task, this is not to say that the average woman doctor can cope with the rough and tumble of general practice. It is said that at the Royal Free Hospital where the majority of the appointments are held by women, that the work is done by them in a most satisfactory manner. It has been a belief held for years, but perhaps after all this is only a tradition, that women are hampered by certain physical disabilities, and it might be interesting to learn what Sir Almroth Wright has now to say on the subject. In any event it is certain that women are flocking to the medical profession in large numbers, and that this constitutes a problem which must be faced squarely and fairly. There is likewise no doubt that there is plenty of scope for the exercise of their abilities in the medical profession. For public health matters, child welfare, and for some other branches of preventive and curative medicine women are peculiarly well qualified by the genius, intuition, and physical characteristics of their sex, putting on one side any special aptitude they may display for a particular branch of medicine or surgery.

THE TREATMENT OF CANCER.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—May I be permitted to refer to one or two remarks contained in Dr. Percy Robinson's letter in the MEDICAL RECORD of October 2, under the heading of "Potassium Nitrate Treatment of Cancer"; and to reply to questions he has put to me?

In the first place, I am glad to note that he agrees with me, and with other writers on the subject—Dr. Bulkley for instance—that "the disease is dependent upon the *condition of the blood.*" I would have been better pleased had he placed the adjective "vitiated" before the word "condition" instead of at the end of the paragraph. Then we should have arrived, in a few words, at the true cause of cancer; because healthy cell metabolism cannot possibly coexist with autotoxæmia, or maintain that normal *metabolism* which is, in these circumstances, replaced by cell *metamorphosis.* And if Dr. Robinson will take the trouble to refer to the MEDICAL RECORD of June 5, 1915, he will there receive my answer to his statement, that I do not state "what cancer is."

My old friend, Dr. Braithwaite of Leeds, advanced the same theory, that Dr. Robinson now propounds, over twenty years ago. He believed cancer was due to the ingestion of too much salt, NaCl. But this theory, so far as this country was concerned, fell to the ground as untenable.

With regard to a statement I made in my letter, which he describes as the "heritage of an old wife," I may assure him that at the Battersea Hospital, eight years ago, I made experiments with this salt of potassium upon several cases of cancer, but unfortunately with only negative results. On these several occasions I followed the old wife's recipe, and ordered one ounce of nitrate of potassium to be stirred up and thoroughly mixed in a pound of molasses: a teaspoonful—which would thus contain about three grains of the salt—to be taken three times a day after meals.

Now we know that potassium is present in all vegetable products, just as chloride of sodium is contained in all animal juices; and that the former is therefore taken into our bodies along with uncooked vegetables and fruit. It is ingested in the form of *organic,* not chemical salts; and in sufficient, though minute, quantities to supply the needs

of the blood; but simultaneously, with the vital principle present in these articles in their natural ripe condition. They have been sufficiently cooked by the sun. But there are other important vegetable salts present, which are quite as essential to the maintenance of a healthy condition of the blood, as potassium is, viz., those of calcium and magnesium, to which I attach great importance, both as preventive and therapeutic agents when cancer is concerned; and without the presence of which the functional activities of the blood would be sadly handicapped. Of course there are other salts present in our food, such as iron, silica, etc., which also have their part to play in promoting the continuance of a healthy blood stream. Those of calcium and magnesium, however, I look upon when administered in the colloidal form or, if this form is unobtainable, in minute doses, as of great importance in the treatment of cancer, but always in conjunction with a carefully regulated diet, and in this method of dosage I heartily agree with Dr. Robinson.

There is one point, and this relates to a chemical problem, to which he calls my attention, and which I fail to comprehend. He states that when KNO_3 enters the blood, and when it comes in contact with NaCl. their separate formula becomes altered into $NaNO_3$ and KCl, while circulating in the blood. Now these are two basic salts, both having an equal affinity for their acids. How then does the transference take place?

Again, I suppose when Dr. Robinson employs the term osmosis he means endosmosis.

My friend Dr. John Round has recently succeeded in bringing about a complete cure in a case of sarcoma of the kidney, the patient having been discharged from one of our hospitals as incurable. Dr. Round simply restricted her diet to uncooked vegetables and fruit.

In conclusion, I fervently trust Dr. Robinson will not, for a moment, suppose I do not gladly give him credit for the good work he is doing; and for the satisfactory work he has accomplished, and the gratifying results he has obtained. We are all working for the same beneficent cause, but of course we are at liberty to exchange, in an amicable way, our views with each other.

ROBERT BELL, M. D.

3. The Significance of Meningeal Symptoms. A. C. Eastman.
4. Parental Responsibility. Henry I. Bowditch.

1. The Use of Water in Diseases of Childhood.—Fritz B. Talbot states that young infants usually take from 140 to 150 grams of water per kilogram (about 1 1/3 ounces per pound), while adults take about 35 grams of water per kilogram of body weight (½ ounce per pound). The amount required per unit of body weight, therefore, diminishes with increasing age. Experience has also shown that the artificially fed infant usually requires more water than the breast fed infant. These figures should be considered as the minimum. The writer's experience has shown that healthy infants require one-half to one-third more total liquid, and older children approximately one-fourth more liquid than the figures would indicate. Conditions due to too little water in the body arise at various times. The earliest instance is found in newborn infants, and has been called "inanition fever." Another is found in communities where artificially fed infants are given a concentrated food without the addition of water. Summer heat, summer diarrhea, fever, pneumonia, and intestinal intoxication, associated with acidosis, are briefly discussed. The methods of introducing water into the body depend upon the symptoms of the case under consideration. Even when there is no vomiting and during the early stages of febrile diseases, a record of the amount of liquid ingested should always be recorded and added up at the end of each twenty-four hours. In this way only is it possible to know how much fluid the child is receiving. If this is taken into consideration early enough and if the child is given the amount of liquid which would normally be ingested during health, plus the estimated amount lost as a result of the disease, fewer untoward symptoms will appear. Sometimes it is necessary to force water when the child is not receiving enough. Water may be introduced by the rectum. Very little success can be expected from this method when employed during diarrhea when there is excessive peristalsis, but it should always be tried. In other conditions without diarrhea, water may be introduced once in four hours very slowly, taking half an hour to introduce three to eight ounces, according to the age of the child, or it may be administered by the Murphy drip, four to five drops per minute, for periods of three hours. This should be alternated with rest periods of three hours in order to prevent the irritation of the rectum and the starting up of peristalsis. Water may be introduced subcutaneously, intravenously or intraperitoneally. The water thus given should be absolutely sterile and should be isotonic with the blood, that is, a normal saline solution. From three to sixteen ounces may be introduced at one time into dessicated children.

1. A Series of Foreign Bodies in the Bronchi and Esophagus.—Henry Lowndes Lynah calls attention to the difficulties often encountered in the removal of foreign bodies from the food and air passages, and also the comparative ease with which many of the uncomplicated foreign bodies may be removed. He reports, with illustrations, twenty cases of foreign bodies in the air passages and seventeen in the esophagus. Out of this series of foreign body extractions there has been one failure to remove the foreign body at the first trial, and there were three deaths. The failure was an attempted extraction of a deeply-located shawl pin in the dorsal branch of the right lower lobe bronchus, the point having penetrated through the bronchial wall of the opposite side. Of the three deaths, two occurred shortly after bronchoscopy. One was moribund on admission and would have died shortly with or without examination, and the other, an infant, had pulmonary edema at the time of the bronchoscopic examination, which continued up to the time of death. The third death was due to the retention of a piece of peanut kernel, which caused septic bronchitis and pulmonary abscess, death ensuing six weeks later. General anesthesia was not used for any of the extractions. Cocaine, ten per cent., was used for the bronchoscopic examina-

tions in adults, and no anesthesia for the esophagoscopic examinations in children.

3. The *X*-Ray as an Essential Guide for Producing Artificial Pneumothorax in Advanced Cases of Pulmonary Tuberculosis.—David Dudley Krupp advocates the consideration of the following points before producing pneumothorax: 1. The extent of the pathology, especially as to cavities. 2. Will the opposite lung be able to furnish sufficient pulmonary tissue after the affected lung has been collapsed without throwing additional risk to the patient? 3. Pleurisy and adhesions. Of 453 *x*-ray examinations made in the last three months, forty-six were bedside examinations. The hand fluoroscope was also used. The remaining cases were examined stereoscopically. With this large number of cases to choose from for the production of artificial pneumothorax, the writer found the problem less difficult. Three selected cases which he followed by a series study of *x*-ray plates, are reported and illustrated. In compressing the affected lung, the walls of the cavities are put in apposition and become fixed together, and the desired results—giving the patient the feeling of wellbeing and comfort—are obtained. Since the symptoms are lessened and comfort increased, artificial pneumothorax is an excellent adjunct, in Krupp's opinion, to the other treatments of pulmonary tuber culosis in advanced cases, in association with röntgenologist, who gives the clinician the guide to the successive steps taken for collapsing the lungs. One must not forget the possibility of acceleration of the tuberculous process of the opposite lung, when one lung is collapsed and a burden put upon that lung to functionate and take care of the toxemia from the affected lung.

13. Benzyl Alcohol for Toothache. David I. Macht.

1. The Etiology of Dengue Fever.—Charles F. Craig, in view of the recent discovery by Noguchi of the probable cause of yellow fever, and of the reported prevalence of the disease in epidemic form in Alabama, summarizes present knowledge regarding its etiology. He believes that dengue fever is caused by a parasite very closely related to that causing yellow fever. As it is practically proved that the latter disease is caused by a spirochete, *Leptospira icteroides*, the search for a similar organism in the blood of dengue patients, using cultural and animal experimentation methods followed by Noguchi in his demonstration of *Leptospira icteroides*, is believed to offer the most promising chance of demonstrating the causative parasite of dengue. As long ago as 1906, Ashburn and the writer believed this disease might be caused by a spirochete, and in their work they used every method at that time available in their endeavors to find such an organism in the blood of dengue patients, but without success. The anaerobic culture methods devised by Noguchi, so successful in cultivating spirochetes, together with improved methods relating to animal experimentation, are powerful aids to the investigation of disease; and it is believed that if properly applied in the study of the etiology of dengue fever it will be only a question of time before the causative parasite is discovered.

5. Progress in Nephrectomy.—Edwin Beer and Abraham Hyman base this communication on a series of 207 nephrectomies, the majority of which have been performed since the reorganization of the surgical service of Mt. Sinai Hospital in 1914. Of the 207 nephrectomies in this series, 189 were primary, 18 secondary; 199 were lumbar extirpations, 8 transperitoneal. Subscapular nephrectomy was performed twelve times. Two of the eight deaths occurred after secondary nephrectomy. The causes of death were hemorrhage (2 cases), renal sufficiency, pyelonephritis, sepsis, shock (suprarenal), general debility, tetanus, (1 each). The technique of nephrectomy is described and the eight fatal cases briefly recorded.

7. Destruction and Repair in Pulmonary Tuberculosis.—Bertram H. Waters reports four illustrated cases and emphasizes the following points: 1. Variations in the clinical behavior of patients ill with active pulmonary tuberculosis are frequently indicative of their diminished resistance and the progression of their lesions. 2. Such variations, though slight and apparently negligible, may be as important indications of progression of the disease as are similar variations of its conception. 3. Such variations should suggest the importance of careful reexaminations which frequently disclose retrogression of the lesion before the advent of more marked symptoms, and make possible helpful modifications of the management of the patient. 4. Roentgen findings, and especially stereoscopic studies, should be employed in addition to physical examination.

12. The Blood Alkali Reserve with Experimental Infections.—Edwin F. Hirsch, in a brief preliminary report, states that the blood alkali reserve of animals injected with bacteria is lowered coincidentally with the initial leucopenia, and during the subsequent increase of the leucocytes rises to or exceeds the level determined originally for the animal. These changes occur within relatively short timed intervals. Graphs of these reactions resemble in contour those generally known for immune body production.

7. Orbital Cellulitis. A. Lewis McMillan.
8. The Place of Industrial Medicine in Medical Science. Frank Shufflebotham.

3. The Value and Interpretation of Some Physical Measurements.—Heald and Thomson call attention to the fact that of recent years two particular methods of measurement, devised to assist in the assessment of physical condition, have been developed by medical physiologists: (1) the comparison of the vital capacity with the dimensions of the body (Dreyer); (2) the measurements of expiratory force and breath-holding (Flack). The data obtained by the two tests were not always in accord, and it therefore seemed to the writers to be desirable to carry out investigations with the object of finding some method by which the tests could be brought into agreement, as both sets of measurements were considered to give information of great value as to the physical condition of the respiratory organs. The results of these investigations are given. These results, as the writers point out, are at present applicable only to male adults ranging between the ages of 18 and 28, and with the weights of 47 to 85 kilogrammes. It is not unreasonable to suppose, however, that the principle developed for combining measurements of physical proportion and of respiratory condition or tone is capable of extension to other ages, to the female sex, and to the other systems of man.

4. The Induction of Premature Labor.—Sir John Phillips collated all the cases occurring in his private practice in which he has performed the operation of induction, and has watched the case during the whole of the month. He also includes the cases which he has seen in consultation, and has carried out the actual in-

duction. They total 161. In these 161 cases of induction of labor there were 7 maternal deaths (4.3 per cent.) and 24 fetal deaths in 164 children (14 per cent.). The causes of maternal death were acute bronchitis, multiple fibroid with twins; contracted pelvis and acute yellow atrophy; ventrofixation and bilobing of uterus; placenta previa; acute albuminuria and eclampsia. In cases where rapid delivery in a primagravida was necessary, such as in puerperal convulsions and complete placenta previa, it would, perhaps, be preferable to perform cesarean section, but should the case be that of a multipara digital dilatation and a de Ribe's bag would be the best course to pursue. If there is no urgency and the case can be taken deliberately, bougies, followed by digital dilatation or a de Ribe's bag, is the preferable course.

5. Clinical Manifestations of the Mobile Proximal Colon.—John Morley, in order to elucidate the question of the clinical importance of abnormal mobility of the cecum and ascending colon, briefly recalls the light thrown upon the subject from the different angles of human embryology and of comparative anatomy. He then discusses manifestations in acute abdominal emergencies (ileocecal volvulus and intussusception) and chronic manifestations. The ideal method of dealing with the mobile proximal colon is to fix it back in the right loin in the position which is the normal one for the orthograde primate. This may be done by the method of Coffey, or by the method recently described by Waugh. A considerable experience with the Coffey method convinced the writer that it is often very difficult through the ordinary right rectus incision to fix the colon in a way that approximates to the normal; and there is the further difficulty that fixation by firm and unyielding scar tissue is a poor substitute for the firm but elastic support afforded by the normal peritoneal fixation of the colon. Accordingly, he adopted the alternative course of reducing the load of the overburdened cecum and ascending colon by the simpler method of plication. After removal of the appendix, a continuous suture of fine thread picks up the anterior and lateral longitudinal teniæ from the base of the appendix, and is carried as far up the ascending colon as the dilatation appears to require. By this method the lumen of the cecum and ascending colon is permanently narrowed without in any way hampering the contraction of the bowel. The clinical results, in Morley's experience, have been satisfactory. Colectomy, either partial or total, should be reserved for cases with the most extreme disability, and should be undertaken only when the procedures devoid of any appreciable danger have failed to give relief.

7. The Influence of Overcooking Vegetables in Causing Scurvy Among Children.—Chick and Dalyell give the following summary of the subject under consideration: 1. An outbreak of scurvy in April, 1919, affected forty children out of sixty-four aged between six and fourteen years under treatment for tuberculosis. 2. From September, 1918, to February, 1919, a good supply of fresh vegetables and milk was available. From the middle of February to the middle of April the daily ration of fresh vegetables was reduced to about 80 grams per head; deprivation was never complete. 3. The eight weeks' period of shortage preceding the outbreak is a much shorter period than the four to six months noted by other observers as necessary for the development of scurvy. 4. It is concluded that though the supply of fresh food was adequate, the diet was nevertheless a scurvy producing one, and that the period of deprivation of antiscorbutic was longer than it appeared to be. 5. An explanation is found in the method for cooking food employed in the hospital which involves a serious destruction of antiscorbutic. Suggestions are made as to means of preventing this. 6. The germination of dry peas, beans, and lentils before cooking is strongly recommended as a means of providing extra antiscorbutic when fresh vegetables and fruit are scarce or absent. 7. It is suggested that abnormally rapid growth may promote the development of scurvy in children.

1. The Value of the Wassermann Reaction in Obstetrics, Based Upon the Study of 4,547 Consecutive Cases.—J. Whitridge Williams, continuing his studies along this line previously reported, bases this communication upon the study of four thousand women and their children who were delivered in the service at Johns Hopkins Hospital, out of 4.547 admissions, between April, 1916, and December 31, 1919. There were 1,839 whites and 2,161 blacks. He discusses, incidentally, the part played by syphilis in the causation of fetal death, considers more fully the significance of the maternal and fetal Wassermann, deals briefly with the value of the microscopic examination of the placenta in the detection of syphilis, and finally says a few words concerning the status of Colles' law.

2. The Cells of the Arachnoid.—Lewis H. Weed discusses the general morphology of the cells lining the subarachnoid space; changes in the cells under physiological activity; changes in arachnoid cells conditioned by age, and ultimate changes in the arachnoid cell-clusters. From his studies he concludes that the arachnoid mesothelial cells are normally of a low flat type, but their morphology depends upon the particular physiological state of the cells at the time of examination. Under the stimulus of particulate matter and in acute infections, the cells increase in size, become phagocytic and at times form free-moving macrophages. Other changes in the growth of the arachnoid cells lead to the almost invariable formation, in the older animals, of cell-clusters, slowy progressive overgrowths, at times undergoing calcification and less frequently seemingly related to the formation of endotheliomata. Hence, the morphology of the cells of the arachnoid may be said to depend not only upon the location of cells (as on the membrane or in an intradural cell-column) and upon the physiological state of the cells (as under the stimulus of particulate matter and infection), but upon the age-condition of the animal (as in the arachnoid cell-cluster).

4. One Factor in the Mechanism of Hemolysis in Hemolytic Anemia.—Clark and Evans, from the results of tests made of the protective power of horse serum against hemolysis of guinea-pig cells by sodium oleate, formulated the following conclusions: 1. The protective power of the serum of normal persons and of patients suffering from a wide range of diseases without anemia is remarkably constant in degree. 2. In anemias of varioue types the protective power of the serum is diminished. 3. This diminution is most marked in anemias which are hemolytic in character and in conditions in which the spleen is involved in the disease process. 4. In pernicious anemia the diminution of protective power of the serum is very striking,

both in degree and the regularity with which it is found. 5. The protective power of the serum in cases of pernicious anemia varies, but seems to parallel more closely the general condition of the patient than the blood picture at the time the titration is done.

2. Abnormalities of the Gastrointestinal Tract in Persistent Constipation in Children and the Application of Roentgenograms in Their Recognition.—Murray B. Gordon considers the *x*-ray a valuable aid in the discovery and diagnosis of any abnormality of the larger intestine which may be responsible for the persistent constipation. Three illustrative cases are reported.

5. Dental Stigmata in the Diagnosis of Obscure Congenital Lues.—William Henry Donnelly calls attention to the difficulties encountered in making a diagnosis of congenital lues in children of the school age, or from six years to puberty. Many children of this age come to the pediatric or nutrition clinic presenting vague obscure symptoms which are hard to account for. In these typical or obscure conditions any available aid in the diagnosis should be made the most of, and it would seem that certain dental abnormalities or stigmata have not been given the attention they deserve as diagnostic points. The classical Hutchinson tooth is comparatively rarely seen even in clinics with a large attendance, and if this particular form of tooth is to be looked upon as the only characteristic one in congenital lues, then many cases will be overlooked or, at any rate, much valuable time will be lost in treatment. The routine performance of the Wassermann test will not invariably settle the diagnosis, as many cases which are clinically luetic give a persistently negative blood test, while, on the other hand, cases which are clinically cured remain "Wassermann fast." Even in the face of a negative Wassermann reaction certain dental stigmata may put the clinician on the right track and turn the tide in favor of the patient. In addition to the Hutchinson tooth many dental abnormalities have been described as associated with congenital lues. Horizontal grooves on the teeth, dental infantilism, cup-shaped erosions on the deciduous molars, and cuspal atrophy of the first permanent molars are signs of diagnostic importance. Abnormal spacing of the upper central incisors of the second set, the incisors being long and somewhat cylindrical, mamillary eminence or accessory cusp on the lingual side of the first upper permanent molar, more recently have been added to the list of signs of luetic heredity. The writer, after careful observation in a large number of cases, believes that the accessory cusp is of more diagnostic importance than the separation of the incisors, although the latter sign is also valuable, and the two conditions often coexist in the same patient. While it is true that these stigmata are sometimes met with in children who are apparently in perfect health, nevertheless, in every instance, their presence is presumptive evidence of congenital lues.

Treatment of Typhus by Injections of Spinal Punctate.—Zielinski of Warsaw briefly outlines this resource, which is not actually new, for it goes back to 1917. He is moved to contribute his article because the treatment has recently been advocated as new by Segal of the Rothschild Hospital, Jerusalem. The author three years ago, in desperate cases of typhus, made a spinal puncture and injected the punctate hypodermically, or intravenously. The first twenty cases thus managed were at once reported and the article was reproduced in several of the leading Teutonic journals. The author persisted in his work and still in the course of the year 1917 was able to report a series of forty-eight cases. None of the reported cases ended fatally. His material climbed to 232 cases during 1918, and his death rate fell to 5 per cent. of those treated. This form of autotherapy has also been tested with more or less favorable results in erysipelas, cerebrospinal meningitis, recurrent fever, scarlatina and abdominal typhus. Another Polish practitioner, Biernacki of Lublin, has not lost a case of typhus since he began to use this method. The author, as stated, uses his method only in the graver cases; thus his 232 patients were selected from a total of 1630 treated in Warsaw hospitals during 1917-8.

Two Cases of Hodgkin's Syndrome in Bahia.—Torres relates these in much detail. The first was in a man of 38, native white Bahian, who appeared with enlarged lymphnodes in the "subclavian" region of slow evolution. There is evidently a misprint involved, as the later history locates the mass in the supraclavicular triangle as an isolated tumefaction, apparently confined to the left side. It seemed evident that the enlarged nodes were continuous with others in the anterior mediastinum. This diagnosis was verified with the *x*-ray. The general condition was poor. The blood count showed marked changes, but no diagnosis was made from it. A puncture fluid was negative to cultural efforts and animal inoculation. Syphilis and tuberculosis were both readily excluded. The growths were extremely hard and the pain was so marked as to require morphine. A cachectic state developed rapidly and this with compression of the bronchi terminated the patient's existence. The second patient was a duplicate of the first in most respects, of the same age and activity, with lesions in the same region, but with a tendency to involve the superficial adjacent territory as high as the occiput. The accompanying illustration shows that the left side alone was involved. It does not appear that the mediastinal glands were involved and this patient had clearly had syphilis. A guinea pig inoculated with puncture fluid died of a pasteurellosis. Tubercle could be excluded. Intensive antisyphilitic measures with use of *x*-rays may have arrested the progress of the tumors, but did nothing further. The blood picture was of the type of the first case. The diagnosis was evidently made by exclusion of actinomycosis, tuberculosis, etc., but in an older case of the same diagnosis (lympadenia) autopsy revealed tuberculosis.

Revue médicale de la Suisse romande.

Eye Symptoms of Mesencephalitis Epidemica, Narcoleptic Form.—Verrey-Westphal has devised one more name for lethargic encephalitis. He reports but two cases, each of which showed the same unusual expressions of ocular disturbances. The first presented an atypical homonymous and vertical diplopia. Examination showed pupils reacting normally and beginning atrophy of the optic nerves. The latter seems to have been a coincidence as this condition was known to exist as a familial affection. Later there was seen to be paralysis of convergence and accommodation. The second patient exhibited accommodative paralysis with homonymous diplopia. A study of literature shows that the following ocular symptoms occur in the disease: paralysis of convergence, paralyses of divergence, paralyses of pupillary reactions to light and to convergence, paralyses of looking up and down, and ptosis. The author asks if most of the ptosis is not purely functional? It is nearly always double although if organic there should be more unilateral cases. Closure of the lids to insure the act of sleep is purely physiological. If the eye muscles are paralyzed through nuclear lesions it is still possible for the pareses to be functional and careful tests seem to exclude in certain cases the existence of organic paralyses.

Book Reviews.

PLASTIC SURGERY: ITS PRINCIPLES AND PRACTICE. By JOHN STAIGE DAVIS, Ph.B., M.D., F.A.C.S. Instructor in Clinical Surgery, Johns Hopkins University; Assistant Visiting Surgeon, Johns Hopkins Hospital; Visiting Surgeon and Plastic Surgeon to the Union Protestant Infirmary, the Hospital for the Women of Maryland, and the Children's Hospital School, Baltimore, Md.; Fellow of the American Surgical Association, the Southern Surgical Association, etc. Octavo of 770 pages with 864 illustrations containing 1637 figures. Philadelphia: P. Blakiston's Son & Co.

FOR a number of years the author has been devoting special attention to plastic surgery, hence is peculiarly qualified to cover this subject *in extenso*. As he says in his preface, few general surgeons do plastic surgery as it should be done; and we might also add that but relatively few ever will do really first-class plastic surgery, for it requires not only technical skill in the use of knife and needle, but also innate powers of imagination, and mental visualization of the effects of possible steps in plastic repair such as is possessed by but few. It has been said that true musicians are born, not made; and the same might almost as well be said of the plastic surgeon.

In most operative surgery textbooks but scant attention is given to plastic surgery, and in none that we have seen is the subject covered in anything like the completeness which we find here. After preliminary chapters giving an historical review and covering general considerations and prosthesis, Davis devotes approximately 100 pages to an excellent discussion of the transplantation of skin and other tissues and the methods of preparing and handling pedunculated flaps.

The chapter on the treatment of wounds, while admirable in many ways, contains much that seems somewhat out of place in a book on plastic surgery; and the same may be said of the chapter on intractable ulcers and varicose veins. With the next chapter, on scars and keloids, the author returns to his proper field and sticks to it throughout the rest of the book. A chapter of about 25 pages is devoted to malformations, and there are additional chapters on exstrophy of the bladder, epispadias, hypospadias and atresia of the vagina. In the chapter on harelip and cleft palate the usual operations are discussed, as well as directions as to when to operate, the proper sequence of operations, pre- and post-operative care, etc. The balance of the book, comprising nearly 400 pages, is devoted to plastic surgery as applied to various regions of the body, special chapters being devoted to the eyelid, ear, nose, jaws, lips, cheek, neck, trunk and extremities. Each section is well covered, there is an extensive bibliography, and the book is replete with illustrations and diagrams. Some of the diagrams seem to the reviewer to be more or less fantastical and impractical, it is true, principally, however, in cases where old methods which should long ago have been thrown into the discard are being perpetuated.

While there are occasions where we differ with the author as to the best method of accomplishing a certain result, these are the exception rather than the rule. The book as a whole is a masterpiece and should be of inestimable value to all who do plastic work, whether much or little; for it appears to us by far the best work extant on this subject.

EXOPHTHALMIC GOITER AND ITS NONSURGICAL TREATMENT. By ISRAEL BRAM, M.D., Instructor in Clinical Medicine, Jefferson Medical College Philadelphia; Physician on Visiting Staff of Philadelphia General Hospital; Member of the Society for Study of Internal Secretions, etc. St. Louis: C. V. Mosby Company, 1920.

THE latter part of this title is what particularly arouses one's interest. There are many books on Graves' disease, and the general facts as to its etiology and symptoms, so far as they are yet known, have been treated of at length in many volumes. But the thought which this title suggests, that the disease can be cured without resort to the knife with its discomfort and even danger is one that inspires the internist with hope. Dr. Bram has no specific to offer, a fact which increases yet more the hope aroused by the title of his book, but presents a well reasoned course of treatment—hygienic, dietetic, medicinal, and local, by means of which he claims to have had signal success in a number of cases.

The book is not, however, confined to the therapeusis of exophthalmic goiter, but the entire ground is well covered, half the book, or over two hundred pages, being devoted to the anatomy and physiology of the thyroid gland, and the etiology, pathology, pathogenesis, symptomatology, etc., of toxic goiter. A very full table of contents and excellent index add no little to the value of this really well worth while book.

OPERATIVE GYNECOLOGY. By HARRY STURGEON CROSSEN, M.D., F.A.C.S., Associate in Gynecology, Washington University Medical School, and Associate Gynecologist to the Barnes Hospital; Gynecologist to St. Luke's Hospital, St. Louis Maternity Hospital, and Bethesda Hospital; Fellow of the American Gynecological Society and of the American Association of Obstetricians and Gynecologists. Second Edition. St. Louis: C. V. Mosby Company, 1920.

As the title indicates, this work has to do solely with gynecological operations, with the surgical treatment of the diseases of women, the discussion of the pathogenics, symptoms, etc., of those diseases having no place in the work. This does not exclude pathology, however, for it is upon this largely that the indications for one or another operation are founded, and the author goes deeply into the operative indications. He warns, indeed, against the practice of one disease one operation. The routine surgical treatment of the diseases of women or of any diseases for which the knife is necessary is as indefinable as is the habit of the careless internist of giving his favorite prescription for stomach ache or for a cough without considering the possible pathology back of the colic or the cough. The sections on the selection of operative measures in the treatment of the various conditions are indeed of equal value to the young practitioner with those dealing with the operative technique.

The illustrations, eight hundred and thirty-four in number, constitute a striking feature of the work. They are all original and are excellently executed, and serve well to elucidate the text which is itself very clear and easily understandable.

HYGIENE, DENTAL AND GENERAL. By CLAIR ELSMERE TURNER. Assistant Professor of Biology and Public Health in the Massachusetts Institute of Technology; Assistant Professor of Hygiene in the Tufts College Medical and Dental Schools. With Chapters on Dental Hygiene and Oral Prophylaxis by WILLIAM RICE, Dean, Tufts College Dental School, St. Louis: C. V. Mosby Company, 1920.

IT is with satisfaction that one sees a book addressed to both the dental and the medical profession and its appearance is additional evidence of the gradual rapprochement of these two. The dental schools have for some time been aware of the necessity of teaching their students medicine in order to make them good dentists, and the physician, although not taught the mechanics of dentistry, has of late learned to recognize his dependence in many cases upon the knowledge and the skill of his dental confrère. Both dentists and medical practitioners must meet on a common ground and each must possess the most definite knowledge available upon the interrelationship between abnormal conditions of the mouth and other regions and various and serious systemic affections.

The work before us deals in very satisfactory fashion with all phases of hygiene—of the mouth, of nutrition, of action, of the central nervous system, of reproductions of the school, and of individual establishments; with the prevention of disease, immunity, oral prophylaxis; public health administration, food and water supply, disposal of waste; ventilation, heating, and lighting. The book is of moderate size but covers the ground with all necessary completeness, and it is safe to predict that it will be found of service by all who seek a general knowledge of hygiene without burdening their memories with details of use only to public health professionals.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 21, 1920.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

The Wesley M. Carpenter Lecture. — Dr. GEORGE DAVID STEWART, in introducing the speaker of the evening, said we had been hearing a great deal lately about internationalism and about what internationalism was going to do for the world. Already the word did not come so triumphantly from the tongue. We began to realize that it came from the brain of socialism, and that a healthy nationalism was a prerequisite to internationalism. We were beginning to recognize that a man must be a citizen of no mean city before he could vauntingly boast of being a citizen of the world. But whether that was true or not, he thought there could be no doubt that the fact that a number of Oxford professors had gotten together and agreed to forget all animosities was one of the most promising signs for the future of science and of humanity. This was a prophecy which augured well for the future and would be one of those factors which went to promote the brotherhood of man. To those who had held the torch high it was a source of satisfaction to know that it had not been thrown to falling hands. We had with us one of whom it might be said that no one had held the torch so high, one who had adorned the literature of the profession wherever he had touched it. He knew of none who excelled him in delicacy and accuracy of technique. Most of those present were familiar with his writings and knew that they were weighty and powerful, and his bodily presence was exactly the same as his writings, in proof of which he took the greatest pleasure in introducing Sir Berkeley Moynihan of Leeds, England.

Gastric Ulcer and Its Treatment.—Sir BERKELEY MOYNIHAN, C.B.M.S., F.R.C.S., of Leeds, England, delivered this lecture, which he prefaced by an apology for having appeared before such an audience without a carefully prepared paper. This, he explained, was due to the fact that he had received the invitation to deliver the Wesley M. Carpenter Lecture only twenty-four hours before sailing for this country, and an exceedingly rough voyage had prevented his writing a paper while en route. However, it was impossible to consider the request of the president of the New York Academy of Medicine as anything but an imperative command; that and his own desire to come before them constituted his reasons for appearing with so little preparation. Coming to the subject of the evening, he said in part, that no doubt gastric ulcer seemed a strange subject to select for presentation before an audience so distinguished as this. Some would wonder whether there was anything new to be said on the subject, or even any new version of an old truth. In going about New York one saw the demolition of old buildings in order that they might be replaced by better and more modern ones. In the same way in dealing with the subject of gastric ulcer they would have to first use the hatchet and crowbar before they could build the real building in which they wished to live. Much paper and much polity had been expended in the attempt to elucidate the subject of gastric ulcer. Intellectually when they approached this subject they should start afresh and try to disregard that immense heritage of paper that had descended to them from their ancestors. Gastric ulcer had been considered a common disease, easily recognized, and comparatively easy and safe in treatment. The truth was gastric ulcer was a rare disease so difficult of diagnosis that no physician by his unaided effort could approach accuracy of diagnosis in more than 50 per cent. of the cases. Gastric ulcer was an ulcer which lay in the stomach. He did not say that because of his Hibernian origin, but because it was the truth, and because many did not yet understand that truth. He was unable to find in the literature or in watching distinguished surgeons operate any recognition of the fact that gastric ulcer was in the stomach. Every kind of ulcer, gastric, pyloric, duodenal, was spoken of and demonstrated as gastric ulcer. Unless one had his anatomy right, he could not have his pathology and his differential diagnosis right, and if these were not right it was incomprehensible that treatment should be correct. All would agree that the pyloric vein divided the pylorus from the stomach, and that the pyloric white line indicated exactly the location of the pylorus. The pyloric white line always, and the pyloric vein in all but 10 per cent. of the cases, indicated exactly the position of the pylorus. Some might object to taking a vein as an anatomical landmark, for nowhere else in the body was a vein taken as a landmark, because the location of the veins was likely to vary in different individuals, but that did not vitiate the fact that anatomical observation justified the choice of the pyloric vein as a landmark in locating the position of the pylorus. If an ulcer was located above the pyloric vein one was justified in calling it a gastric ulcer. There was no defense for the use of the word juxta pyloric, for in no case had they had any doubt as to the exact position of the ulcer. Ulcer of the stomach was twice as frequent in men as in women. Before one accepted the diagnosis of gastric ulcer one must consider the symptoms that were held to indicate the presence of gastric ulcer. Very careful scrutiny and meticulous precision should characterize their approach to any symptoms of gastric ulcer (and he used the word meticulous as indicating a certain timidity, for a certain timidity should characterize one's approach to the symptoms of gastric ulcer). The first symptom was pain. Pain was characterized in a case of gastric ulcer by absolute regularity, order, precision, and method. It appeared with perfect regularity the day before yesterday, yesterday, to-day, to-morrow and had an almost exact relationship to the taking of food. There was always a consistency in the time of the appearance of the pain after taking food. In three-fifths of the cases it had appeared within one and one-half hours after taking food. The nearer the ulcer to the esophagus the greater the pain. All these statements, it should be remembered, were subject to correction. If the ulcer was in the body of the stomach or near the pyloric end the time of the appearance of the pain after the taking of food was altered. It was early if the ulcer was near the esophagus; later if near the pylorus. If near the liver or the pancreas the pain occurred still later, and particularly if the ulcer was near the pancreas. The kind of meal the patient took altered the time of the appearance of pain. If a person took an indigestible meal the pain appeared early. If the ulcer was duodenal the pain appeared later. If the ulcer was small and free from adhesions and if on the lesser curvature of the stomach one would find that the attacks from which the patient suffered were shorter, but were apt to occur more frequently. Very often the inaugural symptom noted at an interval after a meal was a vague feeling of lassitude, weakness, and possibly faintness. If one summed up all his experience it was a sequence of food, comfort, pain, comfort. Vomiting was a rare symptom in true gastric ulcer. The patients obtained a measure of the stomach in a very remarkable way and kept within the limits of their gastric capacity in a way that was very striking indeed. Vomiting, in the speaker's experience, was a very rare symptom in true gastric ulcer, but a very common symptom in phantasmal gastric ulcer, which had too often been described as real gastric ulcer. Hematemesis was comparatively rare; obvious hemorrhage occurred in only 10 per cent. of the cases, while perhaps 25 per cent. had occult blood in the stools or vomitus. It would be better when hematemesis was present to think of something else rather than of gastric ulcer. Some years ago he had ventured to say that hematemesis was not frequent in gastric ulcer and that expression of opinion had aroused opposition. If one made a new statement bearing a new version of truth or a new truth, it was invariably received in doubt and discussed in hostility. If this was not the case it was not true. Jonathan Hutchinson found in the London Hospital that 80 per cent. of the persons who died of hematemesis suffered from appendicitis and nothing else. Other causes of hematemesis were splenic anema, cirrhosis of the liver, and achylia gastrica, or something else than gastric ulcer. But it was just as well to be certain about terms. When a patient died and the pathologist examined the stomach mucosa he found a fissure or a crack that was the cause of the hemorrhage,

but not an ulcer. In gastric ulcer the symptoms had persisted for years and there was a real organic destructive and constructive lesion. There was an effort at defense that gave rise to the indurated base. If we were to arrive at accuracy of diagnosis we must get the clinical history with the most scrupulous care that was possible for us to do, and when we had made up our minds that we were dealing with gastric ulcer we had to admit that in almost 50 per cent. of the cases it was certain our diagnosis would be wrong. How could we reach a correct diagnosis more frequently? The radiographic examination had led to the correct diagnosis in 90 per cent. of cases. The radiograph alone outweighed in value all the symptoms. It seemed almost an impertinence to talk of the value of the radiograph in the diagnosis of gastric ulcer here where Gregory Cole had made good his claim that gastric ulcer could be diagnosed by the methods he described. By following his method, though they had not been able to reach his perfection of 95 per cent. of gastric ulcers correctly diagnosed, they had been able to reach the diagnosis in 90 per cent. In 80 per cent. the diagnosis of gastric and duodenal ulcer had been made by this method. As to examination of the stomach contents, he had submitted patients for many years to examination of the stomach contents, and until they took up the method of Reyfuss the help they derived from such examinations was negligible. They did it to answer criticism and they had reams of invaluable records of gastric analyses in real gastric ulcer. In one-third of the cases there was hyperchlorhydria; in 40 per cent. the stomach contents were examined over and over and over again and the acidity was normal. In about 25 per cent. the acidity was subnormal, or there was no acidity at all. If one examined an ulcer he would find many things. An ulcer was a stiff, hard, red thing, and especially if it was on the lesser curvature of the stomach, there would be much more fat than there ought to be. Again, if one examined a patient who he thought had gallstones and he found no gallstones—that was a dreadful occurrence, but it did take place—he might find the so-called strawberry gallbladder. They had been examining the bile in those cases for the past few years and they found it sterile in 80 per cent. of the cases. They at first drained such gallbladders. Then they began to remove them and to triturate the walls and they found that the walls of these gallbladders contained streptococcus. They finally came to regard fat as a positive indication for cholecystectomy. The infection was not in the bile, but in the wall of the gallbladder. If one examined an infected kidney he would find that it was surrounded by more fat than a normal kidney. All these deposits of fat were an attempt to ward off infection. That was one of the evidences one found in ulcer. When the *x*-ray plates were made and one thought he had found a gastric ulcer he might find that there was a spasm. That spasm the speaker said he had described over twenty years ago as he had observed it at operation. In an unreal gastric ulcer the spasm was not constant, but in a real gastric ulcer it was constant, and the radiologist could tell whether the spasm was constant or only a temporary affair. A patient might have definite symptoms of gastric ulcer in which examination would show not a gastric ulcer, but a deep red blush at the pylorus due to an appendicitis. It was necessary to realize that the symptoms of gastric ulcer were mimicked so accurately that no one could give an opinion unless the radiologist or the surgeon saw the ulcer. One could not walk by faith; he must walk by sight. If the radiologist or the surgeon did not see the ulcer there was no ulcer. It was important to realize this, for all over the world gastroenterostomies were done that were not necessary. Gastric ulcer was said to be present when certain symptoms were present, and when those certain symptoms were present gastroenterostomy was done. Gastroenterostomy had been done for a large variety of conditions, such as carcinoma of the liver, different types of gallbladder disease, the vomiting of pregnancy, dysmenorrhea, tubal disease, for appendicitis, for carcinoma of the colon, and for many other conditions simply because the diagnosis was made on evidence that would not stand examination.

When the examination of real gastric ulcer was made, what was one going to do? Could medical treatment cure gastric ulcer? He thought there was evidence that gastric ulcer of the chronic type could not be cured by medical treatment. He thought so for certain reasons. It was a very rare thing to find the healed scar of a gastric ulcer on the operation table. He examined the stomach of every case he operated upon if time and circumstances permitted and in over 3,071 operations it was excessively rare to find a scar of a healed gastric ulcer. It was likewise exceedingly rare to find the scar of a healed gastric ulcer at the post mortem table. Another point about the medical treatment of gastric ulcer was whether if an ulcer was healed it remained healed. He thought not. If medical treatment was successful it was successful in curing the attack, but the ulcer would recur. It was easy to cure duodenal ulcer, but nothing was so unlikely as that medical treatment would cure a gastric ulcer permanently. If gastric ulcers were cured by medical treatment did not the results produce such a condition that surgical treatment was required. Intellectually his interests were on the medical side. With good technical training it was not such a difficult matter to make a good operator. His heart was with the physicians, but as physicians we must be able to say here was a gastric ulcer as diagnosed by the physician and confirmed by the radiologist and the surgeon. At the end of three years the physician must be able to say the patient was cured, the radiologist must agree that he was cured, the surgeon must agree that he was cured, and the patient himself must say he was cured. He knew of no such case that could be produced. Where was the evidence conclusive and acceptable that gastric ulcer of the chronic type could be cured and remain cured by persistent medical treatment? If the surgeon got a case of gastric ulcer what was he going to do with it? The operation most commonly practised was gastroenterostomy. Gastroenterostomy was first employed in obstructive cases. It had then been applied to cases in which the ulcer lay anywhere in the stomach. He had done it when the ulcer lay far up on the lesser curvature. If one took 100 patients one would find that one-quarter of them did very well. The others did so badly that a second operation would be required, and 10 per cent. of them drifted into malignancy. The malignancy frequently occurred so much later that they knew it could not have been present at the time of operation. Following gastroenterostomy they then had three classes of patients: (1) Those that did well; (2) those that did not do well, and (3) those that developed malignant disease. Twenty-five per cent. of cures in a condition like gastric ulcer was not nearly enough. He was a disbeliever in the theory that there was a physiological value in gastroenterostomy. It was held by some that a gastric ulcer would heal better in an alkaline medium. There was no evidence that he had ever found that justified anybody in saying that an alkaline medium was good for gastric ulcer. The functions of the stomach were all performed naturally in an alkaline medium; the substitution of an alkaline medium was antiphysiological. If the *x*-ray showed that there was a spasm of the pylorus causing a tightening at the pylorus gastroenterostomy might give relief in that kind of a case. These remarks might lead his hearers to believe he had a quarrel with gastroenterostomy. Such was not the case. It had served them well, but not nearly well enough for the surgery of to-day. The next operation they had employed in gastric ulcer was that of cutting out the ulcer. He had tried excision of the ulcer; at first it seemed to succeed and then the patients began to come back. He then decided that he would no longer do this operation. Destruction with the cautery served quite well, and he thought this procedure should be carried out oftener. Balfour's operation was a good one, but for the moment he employed it only under very special circumstances. If one had a large ulcer involving the lesser curvature what was he to do with it? One could not possibly excise an ulcer of that kind. One could not do even a relatively extensive operation under a condition of that kind. His method of handling such a situation was to make an opening into the duodenum and feed the patient through a tube inserted into the duodenum. He had done twelve such operations and every one of these patients was well and had remained well. Sir James Mackenzie had sent him one patient with the biggest ulcer he had ever seen; it was like the mouth of a letter box, so that

one could put his hand through the lesser curvature. For two years that man was fed through the tube. He had gained fifty-seven pounds and was still at work. That was an operation for occasional use in very severe cases. Another operation was gastrectomy, and lately he had been doing a gastrectomy in virtually all ulcers. He had tried the Polya method, the Balfour method, practically all methods, and was now doing a gastrectomy. He incised the jejunum and anastomosed it with the portion of the stomach which remained after he had removed the involved portion of the stomach up to and beyond the ulcer. A few of their results were shown by the following statistics: In a series of 235 gastric ulcers there were 7 deaths, a mortality of 2.9 per cent.; among 9 cases of pyloric ulcer there were no deaths; among 563 cases of duodenal ulcer there were 3 deaths, a mortality of 0.53 per cent. They had performed 80 gastrectomies with 2 deaths, a mortality of 2.5 per cent.; among 674 gastroenterostomies there were 7 deaths, a mortality of 1.1 per cent. Since February 1, 1920, they had had patients of every category and had had no deaths, so these figures were the worst he could show, and he showed them not because they were good figures, but because they indicated that the treatment of gastric ulcer was a much more serious matter than the treatment of duodenal ulcer. The mortality of gastrectomy was less than 2 per cent. The feeling which burned within him was that we had permitted ourselves to be misled on the subject of gastric ulcer. He had accepted things that were not true because they came from authorities, and unless we put our house in order we were likely to cast dishonor on our profession.

The lecture was illustrated by lantern slides and a diagram showing the speaker's method of performing gastrectomy.

Dr. JOHN A. WYETH proposed a rising vote of thanks, appreciation and best wishes for a safe voyage home in honor of Sir Berkeley, not only because he was one of the great surgeons of the world, but because he was their brother from their mother country. (Rising vote.)

AMERICAN ELECTROTHERAPEUTIC ASSOCIATION.

Thirtieth Annual Meeting, Held in Atlantic City, September 14-17, 1920.

THE PRESIDENT, DR. WILLIAM MARTIN OF ATLANTIC CITY, IN THE CHAIR.

Presidential Address.—Dr. WILLIAM MARTIN of Atlantic City delivered this address in which he said, in part, that progress in physiotherapy had been rapid, and that research had proven many of the contentions that were made more or less empirically in the past. Prejudice had been largely overcome by honest effort to demonstrate that science was and had been the groundwork of their work, thus throwing light in the pathway of those who were afraid to tread therein. The time was now past when one felt that apology was due his medical friends for taking up with "strange devices" when advocating the use of electrical currents. The great world war had proven to be one source of enlightenment in that physical measures force themselves more or less prominently and successfully before the professional vision, and though the struggle was somewhat prolonged and at first more or less doubtful, merit at last won out, which augured well for the future. Those who practised along lines of physical therapy must be teachers? That did not necessarily mean that they should hold college positions, but they must realize that they were facing the world and the medical profession in a way totally different from the average medical man in that they were blazing new trails. It was to be remembered primarily that physiotherapists were internists using a special therapy and therefore using the same methods of investigation, laboratory and other, that the profession in general used. It was a crying need that the coming generation of medical men should be given a chance to learn more of this line of therapy, and where now only a few fundamentals were being taught in a few colleges with short courses, time should be given in the curriculum for a full course of lectures, with clinical teaching that would furnish a real foundation upon which the superstructure of a good professional knowledge could be built. In urging the need of further research Dr. Martin said physiotherapy offered opportunities for research work far in advance of the ordinary practice, and it was essential that they keep in the front ranks by aiding and using the laboratory in every way.

Reports of Standing Committees.—Report of Committee on Direct Continuous Current, Including Electrolysis, Electrochemical Surgery, Ionization and All Apparatus Connected Herewith.—Dr. FRANK B. GRANGER of Boston presented this report and stated that during the past year there was worthy of note only the further use of the progressive or selective galvanism of Lapicque, and a new rectifier for which the claim was made that it transformed the alternating current into a smooth nonpulsating direct current. The report urged that cord tips, electrode connectors, and binding posts for galvanic apparatus should be standardized by this society and that manufacturers should be required to equip their machines with such standardized parts. A protest was made against the indiscriminate use of the sinusoidal current in peripheral paralyses. In advanced reaction of degeneration the judicious use of interrupted galvanism followed by the slow sinusoidal, as soon as the muscular response could be obtained, was the treatment of choice. The sharp, sudden, so-called violent contractions of interrupted galvanism did not work harm, but on the contrary, especially in traumatic cases, was an advantage in the prevention of minute adhesions. Muscular spasm not of central origin might be relieved by placing an electrode connected with the positive pole over the muscle or muscles thus affected. Massage, stretching and exercise could better be given if the above procedure were first employed. Similarly a painful ankylosed joint might be better manipulated if radiant heat were first employed and the combined cocaine and sodium chloride ionization. According to the reports of oculists referring such patients floating opacities in the vitreous had apparently been rapidly dissipated by the use of negative galvanism. There were certain types of neuritis which seemed to be unduly stimulated by the positive pole of the galvanic current. If diathermy were employed after such treatment there would be less after-pain and apparently a shortening of the time of disability.

Rhythmic Currents.—Dr. G. BETTON MASSEY of Philadelphia submitted this report in which he called attention to the employment of rhythmically surging waves in neuromuscular excitation as a new thing in electrotherapeutics from the point of view of the older workers, and said that it represented an important advance that should be fully appreciated. Among the points which this report urged on the members of the association were that wave currents employed for therapeutic neuromuscular stimulation, which consists of surges and periods of rest adapted to the natural physiological action of the part should be called rhythmic current, with the name of the particular current rhythmically surged added. A further study of the number of surges of power per minute needed in the various parts of the body to bring therapeutic stimulation into rhythm with the normal muscular impulses of the part should be made. A rhythm proper to a health muscle or group of muscles might not be the proper one in muscles weakened by trophic starvation.

Report on High Frequency Currents.—Dr. FREDERIC DE KRAFT of New York submitted this report showing that when there was too great an obstruction in the "B" circuit (the patient's circuit) then a large amount of current passed through the "A" circuit, with the result of highly ionizing and heating the air contained in the sections of the spark gap. Hot ionized air was a very good conductor of electricity. The report pointed out that there was a want of proper understanding and appreciation in regard to the elevation of the body temperature by diathermy. The heat produced was directly proportioned to the square of the current strength and to the resistance of the conductor. The resulting quantity of heat was directly dependent upon the duration of the passage of current. In addition to these principles the current density must be taken into consideration. This report comprised a detailed description of the technique of diathermy.

Report of Committee on Mechanical Vibration and Exercise Therapy.—Dr. MARY ARNOLD SNOW submitted this report which showed that mechanical vibration although a recognized therapeutic agent did not as yet occupy its merited place in the practitioner's armamentarium. The reasons for this were that its application was not so spectacular as to ascribe to it a psychical effect, that it was simple of action and that it required keen perception as to the relation of cause and effect and actual manual labor to render its application most effectual. In consequence of this its employment could not be delegated to an unskilled helper if results were sought. The late war gave an impetus to the subject but from lack of investigation as to its capabilities and inadequate equipment not half was accomplished with it that might have been. Too often vibratory treatment was given in a desultory manner and with disregard of technique. A vibratory application must be made in accord with physiological laws and pathological conditions presented. The time of application must not be too limited, and the degree of pressure regulated, usually being limited by the patient's tolerance. Mechanical vibration might be successfully used alone or as an auxiliary measure in the after treatment of fractures, fatigue, muscular atrophy, relaxed ligaments, relaxed and atrophied muscles, atrophic and hypertrophic arthritis, paralysis, myositis—acute or chronic—muscular contractures, spasmodic conditions, not of central origin, luxations, periarticular and capsular thickening and induration and edema after fracture and after the breaking up of adhesions as well as of neuritis of a noninfectious character. The above merely gave an idea of the range of the application of mechanical vibration to the muscular system. Spinal localization in the application of mechanical vibration, while yet incompletely developed, gave such results that it offered a fertile field for research work as to selective localizations and therapeutic application. Mechanical vibration, so easy of application, so definitely beneficial in its action, and so capable of accomplishing all and more than massage which could not be effectually standardized owing to the varying capabilities of the personal equation asked, for a more general recognition from the medical profession whose progressive element was ever ready to increase therapeutic efficiency.

Report of Committee on Dietetics.—Dr. VIRGIL C. KINNEY of Wellsville, N. Y., submitted this report which referred briefly to botulism, solanin poisoning and oxalic poisoning, and then proceeded to the discussion of caloric food values. Reference was made to the work of Hart, McCollum, Steenback and Humphry and others and included a brief discussion of diabetic diets.

Report and Apparatus for Hydrotherapy.—Drs. BYRON S. PRICE and H. H. ROBERTS of Lakewood, N. J., submitted this report which was read by the secretary, Byron Sprague Price of New York, and which showed that the application of hot water to the body caused elimination of carbon dioxide, and also increased intermuscular oxidation. This was best secured by the use of low temperatures in baths as had been proven by the treatment of 500 cases. The use of very high temperatures in hydrotherapy had been proven not only to be injurious to the patient but the benefits of the bath were entirely destroyed or greatly impaired. The disastrous results and consequent disrepute of hydrotherapy had been brought about entirely by incompetent operators and pretenders. For this reason baths and other forms of water treatments should not be given as a routine but prescribed by experienced physicians for the invidiual cases. In the treatment of hypotension and hypertension, the primary effect and the secondary benefit was secured by the use of a full bath of 100° F. and the constant use of friction by a competent attendant during the bath. This should be given for twenty minutes. The last five minutes the bath should be reduced to 75° F. In the treatment of a large number of high blood pressure cases, this form of treatment gave the most uniform and satisfactory results. In the application of hydrotherapeutic measures the desired results can only be secured by the proper standardization of apparatus designed by experienced men. The writer had devised such an apparatus.

Standardization of Physiotherapeutic Measures.—Dr. WILLIAM BENHAM SNOW submitted this report which went quite exhaustively into the consideration of muscular spasm or tension including the causes, local condition, and therapeutic management. He showed that the causes of these conditions were very numerous and complex, and stated that a complete consideration of conditions as they arose offered a more complex and intricate study than at first thought presented itself. The report discussed the measures for the relief and control of muscular spasm most energetic and important of which were the static modalities, the static wave current and static sparks, particularly. Less effective were the sinusoidal and other induced currents acting directly upon the muscles. The high frequency modalities which produced heat and so created muscular relaxation of local tension were indicated in the treatment of spasms caused by local infection and arterial spasm. Radiant light and heat by inducing relaxation were remarkably effective also in relieving local muscular spasm, acting coincidently as did the currents which produced heat, in removing foreign sources of irritation from the involved tissues by increasing local metabolism and also by eliminating germs in many cases as well as relaxing the general tissue tension. Mechanical vibration and mechanical massage were also, the report stated, efficient measures for relieving degrees of muscular spasm together with the other measures referred to when the parts so treated were not too sensitive to pressure. In muscular spasm arising from scars or injuries of the cerebral cortex there is very little if anything that can be done with physical measures. When, however, the origin was due to toxic causes, as arising from excessive protein absorption, and interference with intestinal activity, in the early stages, judicious attention to diet with establishment of systematic evacuations from the intestines, with constitutional treatment were effective in abating the condition in most instances. The particular modalities and the method of application in combination with other measures were discussed with reference to the following conditions: Muscular spasm arising from various congestions or inflammatory affections of the spinal cord, such as locomotor ataxia; chorea, when the spasmodic movements arose from either toxic irritation of the meninges of the cord or brain; affections of the peripheral nervous system; very early cases of nontoxic neuritis; chronic brachial neuritis or sciatica; neuritis or secondary neuritis; muscular spasms as occurring with the various types of arthritis; diffuse muscular irritation associated with muscular spasm due to impaired metabolism, myositis, muscular cramps and soreness; muscular spasm or tension in the alimentary tract; in malignant conditions of the stomach and duodenum; spasm of the cardiovascular system; spasms of the sexual apparatus; spasms of the abdominal muscles caused by inflammatory conditions within. All other inflammatory conditions of the abdomen, as peritonitis, inflammation of the ovaries, intussusception, performation or other inflammatory conditions are relieved of pain and spasm by radiant light and heat or thermal penetration with the d'Arsonval current. An accurate diagnosis, however, of the local condition in all intestinal cases, should determine the necessity or not for surgical procedure, but in connection with all surgical operations of the abdminal cavity, radiant light and heat should be employed over the entire abdomen before and after operation, not only for the relief of pain and the local condition, but also for the reflex effect of heat applied at the periphery to overcome or prevent shock and maintain the tone of the deep spinal centers. Special emphasis was laid on the fact that electric modalities were of especial value in correcting and restoring the functions of the liver. The best of all measures for this purpose was the static wave current applied over the lower margin of the liver and epigastrium. Diathermy and sinusoidalization also served valuable purposes in conditions of torpid liver and also for the induction of fecal evacuations from the colon and small intestines.

Report of Committee on Research.—Dr FRANK B. GRANGER of Boston presented this report in which he stated that it was evident that special research could not be carried on in connection with the ordinary hospital laboratory which generally is overworked with the routine demands of a large hospital. Hence the

importance of a special laboratory where time and workers would be available for careful scientific research. For the ensuing year, studies would be made on the anemias, on vasomotor conditions akin to Raynaud's disease which were receiving diathermy; ulcers of the lower extremity, particularly those of the lower extremity which were being treated either with ultra-violet light radiation, diathermy, or the blue pencil brush discharge, or by a combination of these methods. In exophthalmic goiter exhibiting marked toxicity, they hoped by basal metabolism studies to determine whether any of the physical therapy measures would lessen or remove toxicity as well as the surgical procedures, or whether the employment of such physical measures were contraindicated. An effort would be made to confirm or disprove the contentions of Major Turrell of Oxford in regard to ionization.

Clinical Physiology.—Dr. S. St. John Wright of Akron, Ohio, presented this contribution in which he said the progress of physiology was rapid and revolutionary. A few of the facts given by modern physiologists were reviewed, showing, as Noël Paton said, that "The science of life is the science of protoplasm." The phagocyte was cited as an illustration of what protoplasm was—a scavenger attacking, invading and consuming invading pathogenic cells. It was a defender, a guardian, and had to do with all the functions of life. It was, the essayist showed, no longer enough to examine patients for growths or even minor pathological lesions. No physiological process was entirely unmodified by the presence of bacterial toxins or endocrine influences which modified them. Opportunity for the diagnosis of clinical physiology occurred whenever a patient presented himself to a physician for a well defined disorder. Insidious bacterial invasions might exist long before the patient was cognizant of them. While the intelligence of his clients enabled them to co-operate with the general practitioner it was ignorance largely that kept surgeons busy, ignorance on the part of the patient and of the physician. The educative functions of the physician were in relative abeyance. Public health officials and publications and visiting nurses were doing most of what was being done in this field. It was this condition which led Dr. Wright to offer certain suggestions and to point out that means were within the reach of the profession by which many conditions could be recognized in their incipiency and patients restored to a degree of well-being they had never known before. A vibrator might detect trouble; the faradic current might localize areas of anesthesia, or the static spark might render a body aware of tenderness otherwise unknown.

Experiments in Light Penetration.—Dr. Virgil C. Kinney read this paper in which he described the technique of registering the penetraton of the different rays of light through living animal tissues by means of highly sensitized photographic plates. Experiments were made showing the comparison of penetration between tungsten and carbon filaments which disproved the theory generally held that the carbon filament bulbs beng richer in red frequencies naturally would penetrate to a greater depth and so have a greater therapeutic value than the tungsten filaments. In another series of experiments a 100 watt tungsten bulb was taken as a standard and for comparison the different color rays were used, in some cases interposing ray filter screens. Results showed a degree of fogging only slightly less than was produced by the red ray filter while the area of fogging was smaller. It was shown that plain white light had greater penetrating powers than were obtained by use of filter screens; that blue light had somewhat less penetrating power than red, and that natural sunlight had greater penetrating power than any artificial light that was used. It was a surprise to the essayist to find that while the blood in living animal tissues acted as the most complete red ray filter screens to the 10 ampère arc if this blood and red colored muscle fiber were removed and a white meat free from blood substituted, the penetrating power of the 100 watt tungsten white light the arc had four times the penetrating power of the 100 watt tungsten white light and approximately eight times that of the 100 watt tungsten with a red ray screen. These experiments led the writer to advance the theory that color was simply a sensation and had no material existence; it was produced by the vibration rate of the ether waves and varied according to the change in the wave frequencies. It had always been considered that red rays penetrated deeper into living animal tissues than the other rays of the visible solar spectrum because of their greater wave lengths; as we proceeded up the spectrum we knew that the penetration lessened as the wave lengths decreased, until ultra violet rays with wave lengths of only 3,000/10,000,000ths of a millimeter had very little penetrating power. The writer's experiments seemed to show this theory correct up to a certain point, that was, the 100 watt tungsten lamp gave a very good fogging of the sensitized plate in 30 minutes; interposing a red ray filter screen cut down both the area and density of the plate fogging; the blue ray filter with the same light gave only about one-half the fogging obtained by the red ray filter while the 10 ampère arc, rich in ultra-violet, gave many times the fogging obtained by the blue rays. In explanation of these facts the theory is advanced that red rays do not penetrate living animal tissues to a greater extent than the other rays of the visible solar spectrum because of their great wave lengths but the muscle tissues in most cases are reddish in color and they are full of blood and this combination acts as a most powerful red ray filter screen absorbing most of the other frequencies. The writer believes that some time the following theory may be proven and become a law, namely, light rays in penetrating substances increase their penetration as their wave lengths decrease and their frequency of oscillation increases.

Gastric and Duodenal Ulcer and Their Surgical Treatment.—Dr. John J. Gilbride of Philadelphia presented this paper in which he emphasized the importance of early diagnosis in gastric and duodenal ulcer. In reaching a diagnosis a carefully taken history was often a great aid. Too much stress should not be laid on hematemesis and vomiting. Acute ulcer of the stomach was usually a medical disease. The subacute and chronic ulcers became surgical diseases if competent medical help had failed to effect a cure. In the operative treatment the operator must apply the type of operation suitable for the individual patient. The operation of gastroenterostomy for ulcer of the stomach gave the best results when the operation was located at or near the pylorus, or when the emptying of the stomach was interfered with. Excision of the ulcer should be carried out if this was practical from the size and position of the ulcer. A decision must be made as to whether an ulcer was malignant or benign so as not to perform a needless pylorectomy for the removal of a benign lesion. In the presence of a very large ulcer with extensive adhesions to surrounding viscera, the ulcer should be left alone and only a gastroenterostomy performed; in patients with extensive lesions of the stomach an additional gastrojejunostomy might be advisable. Anterogastroenterostomy was performed only in those cases in which it was not possible to do the posterior operation. As gastroenterostomy was not a physiological procedure surgeons were performing operations on the pylorus, employing one of the methods of gastroduodenostomy whenever possible to do so. Crippling adhesions or other complications even in healed ulcers of both the stomach and duodenum which continue to cause symptoms required operation as well as ulcers that had been medically treated and the ulcer had healed but had not remained healed. Surgeons should not enter into competition to see who could get the best results by their respective methods for treating gastric and duodenal ulcers. The best results could be obtained by team work. Cases that could be cured medically were not surgical cases. The mortality following operation for gastric or duodenal ulcer was not more than two or three per cent. while that following perforation of gastric and duodenal ulcers would continue to remain high if the cases were not recognized at once and operated on within the first twelve or twenty-four hours.

Employment of Diathermy and Galvanism in Management of Sequelæ of Occlusion, Partial or Complete, and Rupture of Cerebral Arteries.—Drs. Edward C. Titus and Frederic de Kraft of New York presented this contribution. (To be published in the issue of November 20.)

The Diagnosis of Gastric and Duodenal Ulcer.—Dr.

JOHN H. BURCH of Syracuse, N. Y., contributed this paper in which he stated that it was true that most advanced cases of gastric and duodenal ulcer presented the classical characteristic symptom complex, but it was not equally true that the cases that presented themselves to the clinician in the early stages of this affection presented this stereotyped, so-called pathognomonia symptomatology. In attempting to make an early diagnosis of gastric and duodenal ulcer the essential points to be brought out were periodicity, actual pain, vomiting, methods of securing relief and bleeding. The absence of the textbook pain of one hour for gastric and three hours for duodenal ulcer should not preclude the possibility of peptic ulcer. Neither should the location of the pain be too seriously considered. The methods employed to secure relief from pain, supposed to be due to ulcer, were likewise not of primary importance from the diagnostic standpoint. Gross pain occurs in about 65 per cent. of gastric and duodenal ulcers and the association of hemorrhage with the ulcer symptom complex is said to make a safe diagnosis of ulcer in 95 per cent. of all cases. Analysis of the gastric contents is of value when considered in connection with the patient's history. The value of the *x*-ray in the diagnosis of gastric or duodenal ulcer may be considered as second in importance to careful case history. In the writer's work both the fluoroscopic and direct serial method of roentgen gastrointestinal examination were used. From a roentgenological standpoint four classes of gastric ulcer were considered: 1. Small shallow erosions and follicular ulceration. 2. The penetrating ulcer, more deeply embedded in the gastric wall and showing a well-defined crater. 3. The perforating ulcer showing a continuation of the destructive process in adjacent structures. 4. Carcinomatous ulcer which did not always present distinct roentgenological differentiation from the penetrating and perforating types of ulcer. The roentgenological evidence most to be depended upon was the so-called niche or incisura and the residue in the stomach at the end of six hours. Other manifestations might be more or less corroborative. Another roentgenological sign of considerable importance was gastric hypermotility and hyperperistalsis. It must be remembered that nearly all the roentgen manifestations might be duplicated by gallbladder disease, adhesions about the pylorus and chronic appendicitis so that the roentgen link must always be welded into the entire clinical chain of evidence to be depended upon.

Personal Experiences in the Treatment of Various Gastrointestinal Conditions.—Dr. B. B. VINCENT LYON of Philadelphia contributed this paper, in which he stated that the use of electricity during the past five years had come rapidly to the fore in the treatment of gastrointestinal diseases, and in chronic gastritis, as a supplement to dietetics and lavage, it had proved a valuable addition to our therapeutic armamentarium. The writer emphatically disagreed with those physiologists who tenaciously held the opinion that the glandulature and musculature of the stomach would not respond to the electrical current, and that the beneficial effects observed were due to psychic effects alone. Electrical treatments might be given both intragastrically and by the percutaneous route, but the former was very much the more efficient. It was now quite generally conceded that the faradic current was useful for retoning gastric musculature, with or without atonic ectasia. The galvanic current seemed to act particularly well as a sedative for abnormal disturbances of gastric sensation, and was particularly efficacious in the treatment of gastralgias and hyperesthesias of nervous origin. It was generally conceded to be the current of choice in the treatment of hyperacidity and hypersecretion. In nervous patients, with secretory or motor, rather than sensory defects the faradic current exercised a psychic effect that was often not accomplished by the galvanic current. The essayist reported brilliant results with the use of the Bergonie apparatus modified by the Naegelschmidt, particularly in those individuals for whom voluntary exercise was impossible, such as those suffering from organic insufficiency of the heart, lungs, circulatory system and kidneys, and also for those individuals for whom locomotion was too difficult, either on account of regional obesity or a massive corpulency of too great weight for their legs to support. For years the better element of the medical profession had frowned upon and tabooed all forms of mechanical therapeutics, with perhaps the exception of the orthopedists. It was high time that this ostrich-like mental attitude be discontinued, and that the profession shake off some of its firmly rooted mental astigmatism and become alive to many of the helpful therapeutic measures that could be mechanically applied. Our therapeutic armentatarium should have added to it the rational forms of mechano-electrical procedures.

Sigmoid Impaction—Its Significance, Pathology, and Treatment.—Dr. FRED. H. MORSE of Boston presented this paper, which was illustrated with lantern slides. He stated that the sigmoid flexure, that portion of the pelvic colon which offered little attraction to the surgeon because of the almost certainty of making matters worse, and where the palliative measures of the general practitioner were likewise futile, was a field that urgently demanded relief. The writer was confident that quite a proportion of patients who were treated for cystitis, prostatitis, hemorrhoids, uterine displacements, and so-called catarrhal salpingitis were the direct results of the pelvic colon trying to occupy the place of the above mentioned organs. In many cases unless the sigmoid could be made to functionate normally or approximately so, malignancy must sooner or later result. If the distortions, bends, and almost kinks with which we had to deal in sigmoid impaction and the conditions about the splenic flexure and descending colon were to be treated successfully therapeutic effort must be guided by what was to be accomplished rather than the too often indifferent use of the electrical and mechanical means upon which we had to depend. It meant that direct rectal application must be made to the seat of threatened obstruction, and this could now be done safely and intelligently since the use of the alternating current had been brought under control so that a large amount of muscle stimulation could be used without any possible harm to the inflamed mucous membrane as compared with the interrupted or reversing galvanic current which had been depended upon in times past. The results demonstrated on the screen, the writer declared, were not merely hypothetical theories but legitimate clinical realizations.

Dr. CORA SMITH KING of Washington said she had been using Dr. Morse's apparatus and that the Morse sinusoidal current gave the best results for the colon and sigmoid. In severe cramps either superficial or deep it was very efficient. The use of a very hot Morse electrode, one over the transverse colon and one under the sacrum so as to have as wide a range as possible. Following the use of the sinusoidal current gave a colon irrigation, with the patient in the dorsal decubitus with the hips elevated so as to get the benefit of gravity, which would carry the enema to the transverse colon. The long tube was an unjustifiable violence when gravity would do the work. Following the enema the patient was given galvanism through and through.

Dr. ELNORA C. FOLKMAR of Washington also testified to the value of Dr. Morse's technique. She stated that she found many cases supposed to be gynecological which were but reflexes or extensions of conditions in the sigmoid, and if one took care of the sigmoid many of these other troubles would take care of themselves. Dr. King described her method of treating the sigmoid by passing medication through the sigmoidoscope and by passing the bag and giving pneumatic vibrations.

Dr. G. BETTON MASSEY of Philadelphia emphasized the point that in treating dilatable, hollow organs by the rhythmic current the rhythm must be one of slow waves to allow for separate action from each wave. He believed the alternating current, properly surged, to the sinusoidal current was far preferable to the static wave for this purpose. It was not necessary to apply the current through the rectum in all cases since the sigmoid flexure was immediately beneath the skin and 150 milliamperes applied over the region would do the work.

Dr. CURRAN POPE of Louisville, Ky., called attention to the importance of taking into account the intra-abdominal pressure in dealing with these conditions. He had found light and the static wave very valuable and preferred it for the rectum. He had an electrode which he could pass through the sigmoidoscope into the sigmoid twelve or fifteen inches. He did not make it a

practice to employ enemata at the same time that he was giving the other treatment.

Dr. J. W. TORBETT of Marlin, Texas, said he only used water for cleansing purposes but did not give a constant enema while giving the electrical treatment. He used the galvanic current in many cases that appeared with chronic appendicitis and chronic colitis. He thought there was a habit factor at the bottom of many of these cases of chronic constipation. He had five little rules that he had his patients carry out and continue to practice after they were discharged from treatment. These were: 1. Deep breathing exercises on first waking in the morning, while still in bed. 2. Two or three glasses of water on rising; cold water for hypoacidity and hot water for hyperacidity. 3. Eat coarse food, bran, oatmeal with bran, shredded wheat, something that gave a residue. 4. Regularity in vacuating the bowels, with exercise of the abdominal and sphincteric muscles. 5. Eat fruits and vegetables.

Dr. WILLIAM BENHAM SNOW of New York described an electrode constructed so as to make it possible to introduce it up to the sigmoid. When there was soreness or ulceration of the sigmoid it was better to treat first with the static current, which allayed inflammation and promoted healing. After doing this you could go on and carry out other treatment more effectually.

Dr. ALFRED TENNYSON LIVINGSTON of Jamestown, N. Y., pointed out that many troubles supposed to be stomach disorders were dependent upon pathology in the lower portion of the digestive tract. He had always been opposed to the use of the long tube for the giving of high enema for he thought it had been pretty well demonstrated that it was impossible to pass a long tube through the sigmoid flexure.

Dr. M. L. ARNOLD SNOW of New York spoke of the advantages of using the mechanical vibrator either rectally, abdominally or spinally. In using the vibrator through the rectum as a rule they used it with water, and gave the mechanical vibratory treatment which relaxed any spastic condition that interfered with the introduction of the tube. This treatment was given with the patient in the knee-chest position and was sometimes preceded by an oil enema the night before. In all cases associated with spastic conditions a five minute intrascapular treatment with the ball vibratode affected the bowels and a ten minute mechanical vibration treatment between the first and second and second and third lumbar vertebræ also had a beneficial effect. They had also used the sinusoidal current and the Morse generator to overcome spastic conditions. It might be mentioned that this treatment was contraindicated in the presence of gallstones or acute appendicitis.

Captain C. M. SAMPSON of New York stated that occasionally a case would be found which was intolerant of this treatment. In such cases the bowel should be thoroughly cleansed and diathermy employed together with the sine wave generator.

The Treatment of Scoliosis.—Dr. HARRY EATON STEWART of New Haven presented this contribution, in which he discussed the causes and diagnosis of scoliosis and went rather deeply into the subject of rotation because proper treatment was dependent upon a knowledge of it. In the treatment of scoliosis casts with strong counter pressure from felt pad inserts were necessary in severe cases but they always left the patient rigid and with impaired general health. Removable casts and braces were being increasingly used. L. W. Bacon of New Haven had devised a hinged cast which tended to lever the spine back in place and a manufacturer was now turning out a light hinged brace on the same principle. Exercise was taking first place and gaining favor as our main dependence and should always be used between casts. In any given program there must be included exercises which tended to (a) stretch the concave side, (b) increase flexibility, (c) give bilateral strengthening, (d) correct rotation, (e) re-educate the muscle sense. A program of such exercises was presented. Electrotherapy should also be used. It was good practice to relax spastic muscles by means of the static spark or brush discharge and to employ diathermy for its known effect on nutrition. He felt sure that quicker results would be obtained by using these modalities in conjunction with the treatment by exercises, braces and casts than had been obtained without them. The results obtained by this method of treating scolioses again illustrated how widely electrotherapeutics might be employed in the relief of illness and deformity.

The Spine as an Entity; Its Outgoing Nerves; Its Bony Canal.—Dr. FRANK E. PECKHAM of Providence made this contribution, in which he stated that it was generally conceded that the nerve trunks would transmit impulses. It was a fair statement that such impulses might be started by a faulty working of the physiological machinery either along the nerve trunk somewhere or at its periphery. To him this particular point of transmission was a highly important one because we heard so much about what was called neuritis, which interpreted meant an inflammation of the nerve as an original starting point. Even in an alcoholic neuritis or any other toxic neuritis the point was to cut out the alcohol or eliminate the toxic focus, as the nerve was not to blame. He had seen many shoulder cases treated for so-called neuritis, where there was thickening and adhesions in the soft structures, either due to trauma or to some toxic focus. The treatment was to eliminate the thickening, to slowly stretch out the adhesions, to restore tone to the soft structures and function to the joint structures; thus the so-called neuritis was cured. To think of diseased conditions in the terms of function was an important thing to learn. One must visualize the spine with its many nerve centers, with its outgoing nerves connecting with the various organs, then one could appreciate these impulses being sent over the wire with great accuracy to the exact terminal station selected. It could be done with almost mathematical precision and the results might be counted on with a comparatively high degree of certainty. In arthritis direct vibratory stimulation of the particular nerve center indicated, and which was usually tender on percussion, could be benefited or cured. Many cases of constipation responded to such stimulation applied at the level of the 12th dorsal vertebra and at the tip of the coccyx. The liver could be stimulated by pressure over the 6th, 7th and 8th dorsal vertebræ, as well as by application of the soft brush over the front and back surfaces. The pancreas could be stimulated by vibration at the level of the 9th dorsal vertebra. In arthritis patients the heart was often flabby and dilated. By vibration pressure over the 4th and 5th dorsal vertebræ tone might be restored to this organ so that all symptoms would disappear. The ptoses of the various organs, intestines, stomach, liver, might be overcome by these same methods. That was, tonicity might be restored to the various musculatures and ligaments until position as well as function became normal again. In hay fever and asthma the use of the vibrator over the proper nerve centers could accomplish a great deal. The essayist described the complexities of the spine, composed as it was of a succession of joints, and showed how as time went on thickening and limitation of motion might take place as the result of slowing down of circulation and definite mechanical pressure on vessels and especially on outgoing nerves. Thickened ligaments put tension on the movements of the body and made a direct pull on the nerves. This process when once started might continue until a spine might become pretty well stiffened. The treatment of these cases was to dissipate the thickening, restore flexibility and restore motion and rotation. This could be done by the various physiotherapeutic measures. The subject was one about which not much was written, but it was a very real condition, producing very definite symptoms, and was relievable by proper physical treatment.

Arthritis and Electrotherapy.—Dr. JOSEPH M. BARSKY of Wilmington, Del., read this paper, in which he brought out the advantages of physical over surgical methods of treatment. He stated that it was now generally recognized that a case of chronic arthritis in which there was no destruction of bone around the joint would respond to treatment by physical measures. In cases in which the arthritis was due to periarticular inflammation they doubtless obtained the best results. Ankylosis due to fibrous tissue bands would practically always yield to persistent treatment. When the *x*-ray showed no calcification in an immobilized joint good results were almost always assured. Even though there might be exostoses, if there was no destruction of bone.

a hopeful prognosis might be given. Hygienic measures were essential, proper cleansing of the intestinal tract, supervision of diet, and treatment of the underlying cause must all be included. But the ankylosed joint could be successfully mobilized by measures applied directly to it. The deKraft blue pencil effleuve made an excellent preliminary step, since it accustomed the patient to the apparatus and also relieved pain. The indirect spark and the Morton wave were also brought into play, and diathermy had a place in those cases in which there was no calcium demonstrable. These in combination should constitute the treatment. This might be followed by manipulation and then by the static modalities. As the case progressed intensity of treatment increased until a reaction occurred. Then the treatments were gradually diminished until the reaction subsided. Radiant light and heat was a valuable adjuvant which should not be neglected. This line of treatment must be modified to meet the needs of the individual case. In the treatment of gout electrotherapy had proven its value. Autocondensation to reduce the blood pressure and aid the general metabolism, the static brush discharge over the affected joint and limb for the relief of pain, the Morton wave over the liver—the probable origin of the disorder—diathermy of the affected part, radiant light and heat to the affected part, combined logically, would, even without drug treatment, often effect a cure. Colchicum might be passed directly into the part by ionization. The hygienic treatment was also of importance. The physician must determine himself in a large majority of cases of toxic arthritis whether electrotherapy would help or harm. It might safely be employed in most cases in which the causative lesion was of a low grade character as in those due to an abscess around a tooth root, or it might be employed with great success in those conditions designated by Snow as "rheumatoid arthritis." In traumatic arthritis electrotherapy came into its own. Sprains and luxations always responded to this treatment and the patient would recover more quickly than under any other form of treatment. Illustrative cases were cited.

Dr. WILLIAM BENHAM SNOW of New York stated that there was no treatment for rheumatoid arthritis as effective as the static current. In cases of rheumatoid arthritis of traumatic or infectious origin there was no need for strappings or bandaging of any sort. Nature might fail to reduce swelling and absorb exudate, but the static current was effective, and sometimes achieved the result in one sitting. In all these cases local treatment was accompanied by the use of the static wave current over the liver.

Dr. FREDERIC DEKRAFT of New York emphasized the importance of the use of the static wave current over the liver. He had seen many painful shoulders get well with only the wave treatment over the liver and no treatment whatever applied to the shoulder. The blue brush discharge had not merely a local effect but a constitutional effect.

Diathermy as a Therapeutic Agent, especially in the Treatment of Sprains, Fractures, Adhesions, and Chronic Stiff and Painful Joints.—Dr. ELNORA CUDDEBACK FOLKMAR of Washington, D. C., presented this communication in which she stated that a therapeutic measure for the purposes of this paper was defined as one which aided nature on her own plan to restore physiological function which for some reason nature had not been able to initiate, or did so only in a feeble way. Such an agent was diathermy. Nature's cardinal method of restoration was the production of heat—inflammation locally, fever systemically. No injury, whether traumatic, chemical, thermic, or bacterial could be recovered from except through the agency of heat, whether the heat originated within the system or was induced by external agents. Diathermy increased the temperature of the tissue, dilated the blood vessels by direct influence and increased the blood supply to the area treated; it quickened the chemical processes of metabolism and thus aided nature in making a cure. It relieved pain and tenderness by relieving pressure from exudates, it softened tissues and made them better conductors of low frequency currents and more susceptible to mechanical treatments, such as vibration and massage. The essayist described in detail the technique of diathermy as applied in the treatment of trauma, visceral adhesions, and chronic stiff and painful joints, and said that personally she followed the diathermic treatment with a surging faradic massage, and then gave what she called the "faradic grip," which consisted in slowly moving the secondary coil over the primary until the patient gave an involuntary sound. This was repeated five or six times and was followed by passive and active attempts at motion. In conclusion, the time had passed when it was necessary to suffer pain for days from a sprain or similar trauma, when it was necessary for one to have a fibrous ankylosis of a joint as a sequela of trauma, of rheumatism or of dental infection. Diathermy was destined to become quite as important to the orthopedist as splints and bandages. The odontologist must call on diathermy to assist nature in repair processes as he now called on radiology to confirm his diagnosis. The surgeon must use diathermy in his fracture cases to promote rapid union and to relieve pressure and pain and must take cognizance of diathermy as a valuable agent for the preliminary and subsequent treatment in pelvic and abdominal operations to prevent the formation of adhesions. The layman already demanded an *x*-ray as a confirmatory diagnosis. He would soon demand diathermic treatments.

The Plight of Petrograd Doctors.—*The British Medical Journal*, quoting from the *Tidsskrift for den Norske Laegeforening* of June 15, depicts a distressing state of affairs among the 800 physicians left of the 4,000 resident in Petrograd before the war. During the recent epidemic of typhus the mortality among the doctors in attendance was between 45 and 50 per cent., whereas the mortality for the whole of the population was only between 8 and 9 per cent. The doctors have been nationalized, are regarded as Government employees, and are disqualified from earning an independent living. Their official monthly wage is, on the average, between 5,000 and 6,000 roubles, plus a double food ration, which includes half a pound of bread a day. They are entitled to one public meal a day, consisting of soup and horse flesh. On this dietary the doctors of Petrograd, during the past two years, have carried out most onerous duties, which have been augmented by epidemics of cholera, dysentery, smallpox, and typhus. Their work is generally done on foot. The trams are so lice-infested that their use entails grave risks of typhus; a horse and vehicle costs about 2,000 roubles an hour, and the few motor cars in existence are not available for doctors.

Polyneuritis in France During the War.—A review of a graduation thesis on this subject appears in the *Journal de médecine et de chirurgie pratiques* for August 10, 1920, xci, 15. The author is Micheleau and the material studied came from the Neurological Center of the XVIII Region. The polyneuritides are divided according to the causation, which may be toxic, toxi-infectious, or autotoxic. Among the simple toxic principles which figure as causes introduced from without are alcohol, lead, arsenic, phosphorus, carbon monoxide, mercury, and bisulphide of carbon. In addition, ergot and the vetches or chick peas which cause lathyrism may be mentioned. Among toxi-infectious causes are typhoid fever, diphtheria, paratyphoid, exanthematic typhus, malaria, etc., among acute diseases; and syphilis, tuberculosis, and leprosy among chronic diseases. Among autointoxications, diabetes, gout, cancer, nephritis, hypertrophic cirrhosis of the liver, and cachexiæ should be mentioned. Beriberi is not included. Polyneuritis is a condition in which the cause is everything, as it is necessary to know this in order to make the diagnosis and treat the subject.

Death of Treub.—This distinguished Dutch gynecologist and obstetrician died recently at the age of 64. He was born in a suburb of Leyden and came from a distinguished family, for one brother was the celebrated botanist in charge of the Botanical Garden at Batavia, while another was the statesman, who was active in the late war. He pursued his studies at Leyden University and was successively a medical clinician and general surgeon before entering his special field. He for a while filled the chair of these branches at Leyden, but accepted the professorship at Amsterdam in 1896. He wrote many articles in Dutch and French. In the latter he published articles on leading obstetrical subjects, apparently reserving Dutch for his gynecological contributions, although his two treatises on gynecology and obstetrics respectively appeared in the mother tongue. These works, both of which went through many editions, made him easily the premier in his native country. The author of the obituary in *Gynécologie et Obstétrique*, 1920 i, 4, states that these volumes became the breviaries of the specialists of Holland. He formed a school of younger people about him, among whom is Mme. Tussenbroeck, one of the best known of her sex to practise these specialties. He was affiliated throughout with France and by his eminence probably kept his chairs at Amsterdam from occupation by some imported German savant. He spoke French like a Frenchman, and among his French masters and friends were Péan, Bouilly, Pozzi, and Richelot. During the great war he was active with both pen and medical service for France, having incidentally founded the Pre-Catalan ambulance. For this he had received special commendation from the Paris Academy of Medicine.

Death of Felix Guyon.—Doubtless many physicians, including the urologists themselves, have believed that this pioneer was no longer living, but he has only recently died at the age of 89, and not from senility but some chronic affection attended with much suffering. He studied at first at Nantes and completed his medical education in Paris, was a hospital surgeon in 1862 and a professor in the Paris faculty a year later. Beginning with general surgery, he was by 1867 one of the best known surgeons in France. Shortly afterwards he had begun to specialize in urology and soon was recognized as the undisputed leader in this province. Most of his successors and colleagues were his pupils. His fame was equal to that of Charcot in neurology, Potain in general medicine, Péan in gynecology, and of other famous contemporaries. The Necker Hospital was the great urological center of France and Guyon was equally eminent as lecturer, clinician, operator, and practitioner. In appearance and bearing he was most distinguished. "Wherever he chanced to enter the world raised its hat," said Segond, one of his most eminent pupils.—*Gazette des Hôpitaux.*

Death by Accident of a French Medical Nonagenarian.—Mature American physicians addicted to reading will doubtless recall the name of Bucquoy, which was once a familiar one in medical literature. He was the dean of Paris hospital physicians and was in the midst of a green old age when stricken down by accidental death, of which no particulars are given. He was remarkable for the number of distinguished medical blood relatives. A descendant of Baron Boyer, he was nearly related to Danyau, Chauffard, and Guillain. Born in 1829, he had in his internate in 1852, as fellow internes, Zambaco Pacha and several others who later achieved distinction. His hospitals were the Cochin, the Enfantes-Malades, and the Hôtel-Dieu. He was made a professor agrégé in the Faculty at Paris in 1863, and on the same occasion Jaccoud and Fournier received a like honor. He became a member of the Academie de Médecine in 1882. Retired since 1895 by age limit from hospital activities, he had continued to devote all his efforts to medical assistance and Academy activities. His best known work was in the provinces of cardiac disease and duodenal ulcer.—*Gazette des Hôpitaux.*

GASTRIC HEMORRHAGE.*

BY J. RUSSELL VERBRYCKE, JR., M.D., F.A.C.P.

WASHINGTON, D. C.

THERE is no symptom so terrifying to the patient or so apt to drive him to at once seek medical advice as the sight of blood and I think it may be safely said that even the calm of the physician himself is apt to be disturbed by the occurrence of a large hemorrhage.

Gastric hemorrhage may manifest itself either in the vomiting of blood or in its passage in the stool in large amounts.

Occult bleeding will not be here considered, but only vomiting, or passage by stool, of appreciable amounts of blood which have a profound effect on the condition of the patient.

There are many causes for the appearance of blood, as trauma, ulcers and erosions, diseases of the cardiovascular system, diseases of the liver and spleen, various constitutional diseases, some acute infections, and others. The two main causes for the vomiting of large quantities of blood at a time are gastric and duodenal ulcer and disease of the spleen and liver. In determining the cause of bleeding one must consider the age of the patient, the character of the blood, the past history of the case and the present associated symptoms, as well as the results of physical examination.

It has been stated by some that cirrhosis of the liver is a more frequent cause of a profuse hemorrhage than is peptic ulcer. I think this may be true if the observation is based on hospital practice of the poorer classes but in private practice certainly ulcer takes by far the first place.

My experience has been that there is little difference in the frequency of hemorrhage in gastric or duodenal ulcer and that duodenal ulcer is as apt to cause vomiting of blood as is gastric ulcer, and that gastric ulcer is as apt to cause melena as is duodenal ulcer.

As a rule periodic attacks of indigestion culminating in profuse hemorrhage indicate ulcer. It is perfectly possible, however, for an ulcer to exist for years without symptoms and then to announce itself by a hemorrhage without previous warning. I have been told of three brothers having gastric ulcer, the first intimation of which occurred in each, at the middle of life, in the same way with a hemorrhage. A tender point, front or back, may be found but much pressure should not be made in the search for it. Often it is not present and the physical examination is negative. If there is doubt concerning a diagnosis it can be cleared up by laboratory tests and the *x*-ray after danger from further bleeding is past. When there has been periodic dyspepsia for years without hemorrhage and the patient is beyond mid-life the occurrence of bleeding may indicate carcinomatous degeneration of a preexisting ulcer. Generally, however, the bleeding of cancer is not so sudden or profuse but is more continuous. Physical examination may reveal a mass or, if not a well defined mass, a sense of resistance suggestive of a mass.

When sudden profuse bleeding occurs at or beyond midlife in one who has not had previous dyspepsia, the first thought should be of cirrhosis of the liver, especially if there is an alcoholic history, and the second presumption should be the possibility of some sort of splenomegaly. In cirrhosis there should be no difficulty in making out change in the liver and there may be evident signs of portal obstruction. So also in splenic enlargement it should be possible to recognize this condition by physical examination. However, the Mayo Clinic states that after their experience in the removal of 65 spleens they are convinced that it is not possible to gauge accurately the size of the spleen from physical examination; and the method of filling the peritoneal cavity with oxygen and then examining with the Roëntgen ray, which method shows plainly the solid organs, has convinced me that a spleen may be enlarged to at least twice its normal size without being palpable.

Two rarer causes of profuse hemorrhage may be mentioned, namely, acute ulcer of Dieulafoy, or exulceratio simplex, and purpura. Acute superficial ulcer is characterized by sudden terrifying vomiting of blood without previous or subsequent gastric symptoms, and it is not usually followed by any recurrence. There may not be such a clinical entity but I believe that there is, although quite rare. I have made two such diagnoses, one of which proved to be an error.

Abdominal purpura should not lead to confusion in diagnosis as there will be other signs of the disease, such as petechiæ or bleeding from the gums or other part.

Other conditions cause the loss of blood usually in much smaller quantities. Violent retching from any cause may finally bring up a little blood and if there be present any congestion of the gastric mucosa the amount will be somewhat larger. The most usual causes for such congestion are alcoholic or other intense gastritis and passive congestion from heart disease.

*Read before Montgomery County Medical Society, Rockville, Md.

It has been stated that swallowed blood from pulmonary hemorrhage or other part of the respiratory or upper digestive tract may be confusing. Such error should not occur in hemorrhage of any amount although it is not uncommon for a patient to be unable to state whether a small bit of blood has come from the stomach, throat, or respiratory tract.

I will now give a synopsis of a few illustrative histories of hemorrhage from the stomach.

CASE I.—Miss M. M., age 38, was seen with Dr. Hurtt Jan. 26, 1920.

Past history: Had slight indigestion periodically for some years, calling it acid stomach. Dr. Sprigg had told her the year before that she had symptoms of gastric ulcer.

Present attack: Has had indigestion and acid stomach for the last three weeks. Coming home on the car last night she became nauseated and when she got home vomited a basin nearly full of blood.

Examination: Very pale, ill-looking, slight woman. Examination negative except slight tenderness in the region of the pylorus. Pulse 120. Hemoglobin 50 per cent; red count 2,530,000.

Discussion: In a young woman who has had previous attacks of mild dyspepsia for some years, with a diagnosis of gastric ulcer made the year before and with a negative physical examination, except for slight localized tenderness, there can be but one probable diagnosis, namely, gastric ulcer. Duodenal ulcer is comparatively rare in women. Cancerous degeneration is a possibility, but such a sudden profuse hemorrhage would be most unusual.

Outcome: Treated in bed for ulcer. March 17, 1920, *x*-ray still shows constant deformity of pylorus so that the ulcer is perhaps not yet healed although there is no occult blood and the hemoglobin has risen to 70 per cent.

Diagnosis: Pyloric ulcer.

CASE II.—H. V. D., aged about 50, seen with Dr. Ernest Mitchell.

Past history: Some stomach trouble of rather indefinite type for some years. Has been a rather heavy drinker in sprees and has been on one for the past week.

Present attack: Started suddenly yesterday, vomiting blood in considerable amounts every few minutes.

Examination: Large well built man, pale. Pulse 140, small and almost imperceptible. Otherwise negative.

Discussion: There are here three possibilities. Hematemesis in a man of middle age who has been a pretty hard drinker would first suggest cirrhosis of the liver of alcoholic gastritis. There was no evidence that the liver was diseased in any way and so cirrhosis can probably be eliminated. Alcoholic gastritis he undoubtedly had, but is that sufficient to account for the severity of the symptoms? I think not, as I have never seen a patient anyway near exsanguinated by bleeding from gastritis. Peptic ulcer is suggested by long continued mild dyspeptic symptoms culminating in the profuse hemorrhage and better fits than any other diagnosis.

Outcome: Patient continued to vomit every time the stomach filled with blood and died several hours later.

Diagnosis: Alcoholic gastritis, Peptic ulcer.

CASE III.—Dr. W. A. Mc., age 50, called me May 10, 1917.

Past history: Always healthy. No trouble with digestion. Has been a very heavy drinker.

Present attack: Has been drinking heavily for a week. Three hours ago he suddenly vomited a large amount of blood. This was repeated 6 or 7 times so that the whole amount has approximated 2 quarts.

Examination: Large heavy man. Acne rosacea and congested face in spite of loss of blood, with small weak pulse of 106. Examination otherwise negative except for blood pressure of 168 and liver enlarged to three fingers below costal margin and quite firm.

Discussion: Sudden severe hemorrhage in a man of 50 with alcoholic history and without other symptoms means, in the presence of enlarged liver, cirrhosis.

Outcome: Relieved by treatment; *x*-ray made one week later showed no abnormality of the stomach. Discharged from hospital May 19, 1917.

Diagnosis: Cirrhosis of the liver. Ruptured esophageal varix.

CASE V.—Mrs. W. L. B., aged 37, seen with Dr. W. P. Carr, June 19, 1919.

Past history: Good health until 5 years ago when she began to have periodic stomach trouble with pain one hour after meals. One year ago had serious hemorrhage. Dr. Carr later operated removing the ulcer. Relieved for two months only.

Present attack: Having the same pain as of old. For several days has been passing large black stools. Dizzy and faint.

Examination: Tender point in epigastrium. Pulse 120, hemoglobin 30 per cent. *X*-ray shows spasmodic hourglass of stomach with ulcer on the lesser curvature.

Outcome: Apparently cured to date of the ulcer after bed treatment for 6 weeks but has never regained all her strength.

Diagnosis: Gastric ulcer with bleeding by bowel.

CASE VI.—K. N., age 16, seen with Dr. Russell several years ago.

Past history: Healthy all life. Never knew he had a stomach.

Present attack: Four days ago was suddenly seized with dizziness and faint feeling and threw up a large amount of blood. There were several repeated hemorrhages so that he was nearly exsanguinated.

Examination: Negative except for pallor, hemic murmur, and feeble pulse of 110.

Discussion: The suddenness of the onset and the alarming size of the hemorrhage without gastric symptoms previously and without any other evidence of disease might suggest cirrhosis if in an older patient with an alcoholic history; however we are able to exclude this malady and there remains only peptic ulcer or acute ulcer of Dieulafoy, the latter of which seems much the most likely.

Outcome: Treated as if for ulcer. A month later his hemoglobin had risen to 65 per cent. He was recovering strength and was discharged without symptoms. Many months after he had had no recurrence.

Diagnosis: Acute ulcer of Dieulafoy.

CASE VII.—Mr. H. A. O., age 29, referred to me by Dr. Henry Fry, Jan. 15, 1915.

Past history: Except for measles and mumps had never been ill in his life. Fine digestion.

Present illness: Five weeks ago he was suddenly seized without warning with three hemorrhages, vomiting over a quart of blood. He was in bed in Chicago and has had no trouble since.

Examination: Negative in every way. Liver and spleen were apparently of normal size. There was no occult blood.

Discussion: Like the preceding case I could explain the sudden hemorrhage without other symptoms in no other way than by the diagnosis of acute ulcer of Dieulafoy.

Outcome: The diagnosis was explained to him and he was told that there was slight chance of any recurrence but to satisfy his mind that something was being done to prevent it I gave him a soft diet and told him to take silver nitrate for the first three days of each month. This he did for 11 months. The next month, March 5, 1916, while in St. Louis he had sudden nausea and faintness and passed large dark stools. At this time his temperature was 100°, pulse 116; hemoglobin 93 per cent., red cells 5,000,000, and white cells 14,000. An *x*-ray study by Dr. Mills at this time was negative. As soon as he could travel he came to me, March 20, 1916. A thread test showed a well localized blood mark on the lesser curvature, about one cm. long. Repeated the next night it was the same. An *x*-ray by Dr. Christie, March 24, 1916, showed the stomach to be hypertonic with irregular peristalsis and an entire lack of peristalsis about the middle of the lesser curvature corresponding to the mark on the thread. Diagnosis was made of gastric ulcer of the lesser curvature with inflammatory induration. He then had ulcer treatment in bed for 3 weeks. After getting about again the *x*-ray was normal but repeated in a few days showed the same absence of peristalsis in a spot about one inch across on the lesser curvature as in the first examina-

tion. Occult blood tests were made at intervals until October, 1917, and were negative. I saw him Oct. 29, 1917, and assured him that he was all right but did not examine him. He then went to New York and the next day passed large black stools and went to the New York Polyclinic under Dr. Bassler. At this time the spleen was 4 times normal size and at least twice normal when he left the hospital. Even after the hemorrhage red cells numbered 5,500,000. Dr. Bassler thought it was Banti's disease. Dr. Soper then treated him in St. Louis with *x*-ray applications to the spleen but he had another hemorrhage Dec. 5, 1917, while taking the treatments. Dr. Soper then thought it was a gastric erosion and treated him again as if for ulcer. Jan. 7, 1918, he had another smaller hemorrhage. He then took a long course of *x*-rays which reduced the spleen somewhat. In November, 1918, he had 5 days of fever and the spleen enlarged again. January, 1919, he took a course of benzol. He has been examined every 60 days and the spleen can still be felt. No cause has ever been discovered, not syphilis, Banti's, tumor, leukemia, or malaria.

Diagnosis: Splenomegaly of unknown origin. Possible ulcer of the lesser curvature in addition.

CASE VIII.—B. E. T., age 38, seen with Dr. George Wood, March 5, 1920.

Past history: Occasional dyspepsia. Otherwise negative.

Present attack: Some gastric distress 6 days ago relieved by vomiting. Three nights ago his wife found him lying on the bathroom floor surrounded with blood. He soon recovered consciousness. Is weak and his head pounds.

Examination: Negative except for pallor, systolic murmur over the whole heart, and pulse of 104.

Discussion: Indefinite, long continued dyspepsia culminating in profuse hemorrhage, without other physical findings warrants a diagnosis of peptic ulcer. Whether gastric or duodenal it is not possible to say.

Outcome: Treated for 3 weeks in bed. No return of hemorrhage and occult bleeding ceased. On getting about an *x*-ray examination showed constant deformity of the duodenal cap. This would seem to indicate that the ulcer is not yet healed, but since repeated occult blood tests are negative it may be that the deformity is due to scar formation.

CASE IX.—H. C., age 33, consulted me Oct. 12, 1918.

Past history: He had been referred to me in 1915 by Dr. Kavenny for indigestion off and on for 2 years. Had pain through the stomach 2 to 3 hours after meals relieved by eating again. The physical examination was negative. He had occult blood, high gastric acidity, and hemoglobin of 45 per cent. He was treated and gradually and steadily improved. Diagnosis was gastric ulcer.

Present illness: For past 2 months, after being well three years, he has been having the same indigestion and has been getting pale and weak.

Examination: Pale, ill looking man. Pulse 120. Left rectus more resistant than the right and there is an indefinite sensation like a slight mass in the region of the splenic flexure. Considerable tenderness across the whole epigastrium. Blood pressure 100 mm. Hemoglobin 50 per cent. Stool mostly changed blood and much blood removed from the stomach by the tube.

Discussion: In view of the past history and the clear-cut former diagnosis the natural conclusion would be that there was a recurrence of his gastric ulcer with hemorrhages passed by bowel. Such a diagnosis was made and operation advised.

Outcome: Dr. Jack at operation found a large mass involving the posterior wall of the stomach and the pancreas. Few enlarged glands. The man died a few hours later from exhaustion.

Note: This case is interesting because of the age of the patient, 33, and the fact that such a large carcinoma should develop without any change in the old symptoms caused by the ulcer itself. The long duration of the freedom from symptoms, however, and the rather continuous bleeding are very suggestive of malignancy.

CASE X.—Mr. G. O. C., age 43, consulted me Sept. 18, 1918.

Past history: Always well until 6 years ago when he had an attack of cramps and soreness about the navel for 2 days. Three years ago consulted me for first time and diagnosis was made of duodenal ulcer. An alkaline powder and soft diet so relieved him that he never came back until the present time. He has had no trouble during these three years.

Present illness: A week ago while on a trip he noticed that he had a large black movement. He felt all right until three days ago, when, after cranking his car violently, he became pale and his head began to pound. Dr. Braden saw him and immediately brought him to me.

Examination: Negative except for intense pallor. Pulse 110, hemoglobin 30 per cent.; the stool was practically pure clotted blood.

Discussion: In view of the past history the diagnosis of duodenal ulcer with hemorrhage is justified. The case is interesting in showing how large an amount of blood can be lost without the patient becoming aware of it if it passes by bowel instead of being vomited.

Outcome: Transfused and treated medically for 5 weeks. After recovery of strength, an *x*-ray examination showed deformity of the cap and also a large filling defect of the greater curvature of the stomach of unknown etiology. the Wassermann test was negative. A few months later he was operated on by Dr. Mitchell who found duodenal ulcer and a growth in the stomach of unknown character and for which nothing was done. Patient is alive and well to-day.

CASE XI.—Mr. B., age 47, seen with Dr. Lindsay.

Past history: Luetic infection at 18. No evidence of any trouble from it until Dr. Lindsay found absent pupillary and knee reflexes last year. Wassermann was positive and tabes diagnosed. For many years he has had a stomach complaint for which he takes great quantities of soda, and without which he states he could not live.

Present attack: Yesterday had salvarsan. At 2 A.M., he vomited first food, then dark coffee ground material, and finally bright blood.

Examination: Pupils irregular and do not react to light. Knee jerks absent. Right kidney ptosed. Cylindrical mass running across epigastrium feeling like transverse colon, spastically contracted, tender. An *x*-ray examination by Dr. Merrit showed constant deformity of the cap with suspicion of a pocket as if of chronic perforation.

Discussion: We know the patient has had lues and that he has tabes. The question is, do these factors enter into the present trouble? We decided not and diagnosed peptic duodenal ulcer.

Outcome: He refused operation and so was treated medically with slight hope of curing the ulcer. All symptoms of his former dyspepsia have, however, been relieved and he has gained 20 pounds in weight.

Diagnosis: Peptic duodenal ulcer with tabes.

CASE XII.—Mrs. J. D. G., age 36, was seen with Dr. Frank Leech, Jan. 9, 1914.

Past history: Has had stomach trouble for 12 years with attacks of pain and gnawing immediately after meals. Positive Wassermann has been obtained at some former time.

Present illness: Three weeks ago she began having worse trouble with her stomach and last night began vomiting blood. She has lost over a quart.

Examination: Very ill, pale woman. Pulse small and running. Physical examination negative.

Discussion: Is this a peptic ulcer or a luetic ulcer? I know of no way of proving the condition except by the *x*-ray. It is an academic point, as the treatment for the hemorrhage must be carried out and this would involve an ulcer treatment. Then any patient who has a positive Wassermann needs specific treatment any way.

Outcome: Improved under treatment. Reported July 2, 1917, that in June, 1914, she had an abortion. Was careful of her diet for 2 years. She thinks that she has twice had small hemorrhages from the bowel. In January, 1917, she had pain and Dr. Leech kept her in bed for the greater part of 5 months.

Diagnosis: Lues, Gastric ulcer (specific?)

CASE XIII.—Miss B. T., age 25, was referred to me by Dr. Kaveney April 1, 1915.

Past history: Always healthy. Never had a doctor.

Present illness: Ten days ago noticed a reddish eruption on her legs which became purplish. This was

followed in 3 days by pains in the limbs and next day in the stomach. For the last 5 days she had vomited everything taken. At first the vomitus was green but lately fresh and clotted blood in considerable amounts. Vomiting is now occurring every few minutes and is preceded by very painful cramps.

Examination: Well built girl. Dependent skin shows marked petechial eruption. There is marked tenderness over the whole abdomen. Leucocytes 52,200; hemoglobin 80 per cent. Five days later she had lost considerable blood and vomiting had continued. Leucocytes were then 18,200, with 80 per cent. polys. The urine contained albumin and casts.

Discussion: The loss of blood by stomach accompanied by cramps and the attendant eruption of characteristic petechiæ can mean only purpura abdominalis. The high leucocyte count would make it appear as if the disease were initiated as an acute infection.

Outcome: April 7 she was given horse serum and all symptoms stopped in a couple of hours as if by magic. The eruption slowly cleared up and her strength was rather slow in returning, but she made a complete recovery and has never had any illness since.

CASE XIV.—Mr. H. T. S., age 41, consulted me Feb. 25, 1920.

Family history: Father had cirrhosis of the liver. Mother supposed to be a bleeder. Sister had cirrhosis of liver at 5 with ascites.

Past history: When 5 years old had dropsy. Has always been considered a bleeder. Nearly bled to death a number of times when growing, especially from nose bleed. Had a period of some years after he was first married of freedom from trouble and was pretty well. Six years ago had large hemorrhage by the bowel. This was followed by ascites. He has had many of these hemorrhages and attacks of ascites since, his hemoglobin falling to 30 per cent. or under. *X*-ray treatments to the liver seemed to help him.

Present attack: Had hemorrhages starting 3 days ago and is very weak. Still passing changed blood.

Examination: Thin pale man with a decided lemon tint to the skin. Pulse 116, hemoglobin 35 per cent., red count 1,536,000. The right hypochondrium is occupied by a large mass which seems to be an enlarged and movable liver. Spleen not felt. The liver dullness extends at least a hand's breadth below the costal margin. Stomach tube shows the stomach filled with blood and the stools are tarry with it. Oxygen *x*-ray shows the liver serrated and enlarged nearly to the crest of the ileum. The spleen is three times normal size with a band of adhesions running from the lower pole to the pelvis.

Discussion: It is evident that the gastric hemorrhage is secondary to disease of the liver and spleen. The exact disease I am unable to name as yet and am still studying the patient. Certainly it is not ordinary cirrhosis, Banti's disease, or splenic anemia. At present I am leaning toward the diagnosis of congenital family jaundice.

Outcome: Will be presented in a more detailed study at some future time.

Prognosis.—There is little chance for the patient to lose his life from the hemorrhage itself if proper treatment is given; and by proper treatment, as will be seen later, is meant largely the avoidance of too much treatment.

If surgery is attempted during or immediately after severe bleeding, the opposite may be true and there is a great chance of the patient succumbing. But one of my patients treated by medical means has died from hemorrhage.

The prognosis for ultimate cure naturally depends upon the etiologic factor and the treatment. I think we are safe in saying that hemorrhage in peptic ulcer, instead of militating against the chances for cure, may have an opposite effect, and an ulcer which has caused hemorrhage may yield to treatment better than a more indolent one.

Treatment.—The great therapeutic trinity is rest, morphine, and ice locally. The first and prime consideration in the treatment of severe hemorrhage is rest in every sense of the word. When this is secured bleeding will usually stop when the blood pressure drops to a certain point. The patient should not move or be moved in the least.

Morphine should be administered hypodermically to marked physiologic effect and that effect should be maintained until the crisis is past. This serves the purpose of quieting peristalsis, helping to maintain the general bodily quiet, and allaying the restlessness and mental worry.

The continuous use of the ice cap is also of importance. How it acts we do not know. Certainly the cold does not penetrate more than ¼ inch into the skin. It may be that in time to come we shall be laughed at for its use, as we in our enlightenment smile at the use of lead and opium wash locally which was so general a few years ago. However, I should not like to do without the ice application in a case of bleeding.

I do not advocate the use of horse serum or other aids to coagulation unless it is shown that the patient's coagulation time is increased. If the blood clots perfectly in normal time I doubt whether we can cause the blood to clot sooner than it otherwise would, that is when the circulation reaches a low ebb.

On the other hand, coagulen or coagulose is most valuable in cases of hemorrhagic diathesis, and should certainly then be used, perhaps thereby swinging the pendulum from death to life.

I might mention a few of the things which are often used in cases of profuse hemorrhage and which I would heartily condemn. Do not give strychnine or other heart stimulant. Death does not result from heart failure in these cases. The lowered oxygenation of the body is a sufficient stimulant to whip up the heart. Far from doing good, such stimulants may be the means of causing the dislodgement of a clot which may have formed.

The same objection can also be raised to the administration of any drug which raises blood pressure on the one hand or dilates the peripheral blood vessels of the digestive blood lake on the other hand. It is best, therefore, to give no drug in severe bleeding but morphine.

So also under ordinary conditions I would not advocate the use of salt solution. While it will stimulate for the time being it will surely raise blood pressure and theoretically I think it not improbable that it might, by diluting the blood, tend even in the least bit to interfere with normal coagulation.

In hemorrhage from a large vessel the giving of gelatin solution, adrenalin, or anything else into the stomach will do more harm than good. They will have no effect in stopping the flow but on the other hand will cause peristalsis which is what we wish most to avoid. The same may be said to be true of washing the stomach with ice water.

These considerations do not apply when the hemorrhage is small and continuous as in steady oozing. In these instances the ice water lavage or local administration of gelatin or adrenalin will be very efficaceous.

Mention has been made above of the necessity of avoiding surgery after profuse hemorrhage. Those of little experience may rush in where sur-

geons fear to tread, but I believe that the best surgeons will not advise operation for serious gastric hemorrhage. In an experience with a number of nearly exsanguinated patients I have lost but one and yet I know had early surgery been practised the mortality would have been very high. After the patient has recovered from the shock of the loss of blood and perhaps built up a bit, surgery can well be utilized in the cure of the lesion and the prevention of further bleeding.

I have not yet mentioned transfusion. We know that to counteract the effect of hemorrhage it is without an equal. The prime question is, when should it be done. I believe each case should be considered as laying down its own rules. It is possible that the donor's blood may contribute some factor which will hasten the formation of a clot, but I am inclined, in case of a large hemorrhage, to wait for its use until the bleeding has stopped, and then to urge its use in building the patient up. In long continued small hemorrhages when the patient's blood has been much reduced it should be used quickly and repeatedly.

THE ROCHAMBEAU.

NOTES ON ADRENAL ACTION.

BY E. H. P. WARD, M.D.,

WHITE PLAINS, N. Y.

A CONSIDERATION of the action of the adrenal glands based upon various disorders affecting them and also upon the pharmacological study of the action of adrenaline suggests in a remarkable way the delicacy and the complexity of the mechanism by means of which the human organism adapts itself to its environment. In my article on The Moon and Insanity (MEDICAL RECORD for August 23, 1919) I outlined in a general way the effect which *climate* may have had in bringing about the peculiar characters of the various races of mankind—a hot climate producing a black, sluggish race; a temperate climate, a yellow race of moderate vigor; and a cold climate, a white, vigorous race; with various intermediate types. Now it seems to me that there is reason to believe that the actual mechanism through which climate acts on the human organism to produce these various modifications consists, in large part at least, of the adrenal glands and the allied chromaffin tissues.

The adrenal glands contain two distinct kinds of tissue—the *cortex*, an epithelial structure whose function is not clearly understood but which is supposed to furnish an hormonic internal secretion which influences sexual development and activity; and the *medullary* portion whose principal active constituents seem to be certain large polymorphous cells which in chromic acid solution take on a brownish pigmentation and are spoken of as chromaffin cells. Similar chromaffin cells are found elsewhere, in the ganglia of the abdominal sympathetic system and in certain structures (the paraganglia) situated along the course of the aorta; also in the carotid glands and perhaps in the coccygeal gland, the parovarium, and the epididymis. Collectively these structures are spoken of as the "chromaffin system"; and the specific function of the chromaffin system and of the medullary portion of the adrenal glands is to furnish an internal secretion known as epinephrin or adrenaline (Osler). Now if we consider the pharmacological action of adrenaline (as described, for instance, by Cushny in his "Pharmacology and Therapeutics") and also the symptoms of Addison's disease and of other disorders of the adrenal glands (as described, for instance, by Sir William Osler in the last edition of his "Principles and Practice of Medicine"), it seems to me a fair inference that the function of these tissues is, in the broadest sense, to adapt the organism to life in a cold climate.

There are two factors by virtue of which climate influences environment. There is, first, the factor of the direct heat and light from the sun, which vary in intensity from the tropics to the poles and also with the altitude and conditions of wind and proximity to water. This factor of heat and light from the sun influences the human organism directly: pigmentation of the skin and eyes is developed to protect the organism from the direct rays of the sun in a tropical climate; and in addition a number of other adaptations are required to fit the organism for life in a hot climate, but we need not consider them here because, since man probably originated by evolution in a hot climate and many of the adaptations necessary to such a climate were handed down unchanged from his animal ancestors in whom they had been developed as an adaptation to environment, we can consider man as adapted to a hot climate as the original type and merely refer to the modifications which were required to adapt him to a cooler climate as he migrated toward the poles. Thus the original human type would be pigmented to withstand a hot climate, but as members of the race migrated to cooler climates pigmentation of the skin and eyes would be less and less necessary; but the air would be drier and colder and modifications in the shape, etc., of the nose and face would be necessary to warm and moisten it on its way to the lungs; and since man is a warm-blooded animal (homothermous), in a cold climate it would be necessary to produce more heat by muscular activity and this would require more vigorous heart action with a higher blood-pressure, and thus the skeletal muscles and the muscular and elastic coats of the circulatory system would be more strongly developed.

The second factor through which climate influences environment consists in the modifications which it produces on the surface of the land, varying from tropical and temperate vegetation to barrenness and eternal snow and ice. These modifications lead to variations in the quantity and forms of animal life of all kinds, thus modifying man's environment still further and introducing new factors in the struggle for survival. Thus the factor of protective coloration is introduced, enabling man to hunt for his food or escape from his enemies with less danger of detection. And it seems a remarkable coincidence that the same pigmentation of the skin that protected man in the tropics from the heat of the sun should serve also to protect him from his enemies by making him invisible in the dark depths of the tropical vegetation; and the same absence of pigment with which he could safely face the sun in a cold climate should constitute a factor of safety and survival by making him also less conspicuous amid the snows of the north. It seems a strange coincidence, and yet not so strange when we consider that these two factors of heat from the sun and the darkness of the jungle exist together in en-

vironment, since the latter is a result of the former, as well as the factors of absence of heat and the whiteness of snow; also moderate heat with a more or less yellow or brown earth-covering in a temperate climate. Since these factors are associated in environment, it is but an example of the wonderful manner in which the organism adapts itself that a single device, pigmentation or its absence, should serve both purposes. Then, too, while in a tropical climate man could readily find an abundance of food but must be constantly on guard against enemies of all kinds, in a cold climate he had to get out and hustle for his food and had to wage constant warfare against the elements. Thus in a cold climate the same physical energy and activity that was required to keep him warm served to provide him with food and to arm him against the rugged forces of nature—another remarkable coincidence.

The point is, then, that man originated in a warm or hot climate as a pigmented and sluggish animal, and as members of the race migrated to colder climates adaptations of form and function were necessary; and that many of these adaptations were brought about by an increased activity of the adrenaline-forming tissues. According to this assumption, cold must act as a stimulus to increase the formation of adrenaline, and heat to decrease it. Now let us consider the evidence and see whether it justifies such a conclusion. It would be difficult to determine directly whether cold increases and heat diminishes the formation of adrenaline in the human organism; but we can infer the amount of adrenaline formed from the degree to which the organism responds to its characteristic action. And if the effect of cold upon the organism is identical with the effect of adrenaline, it is a fair inference that the cold acts by stimulating the formation of adrenaline. Whereas on the other hand, if heat affects the organism in the same way as a hyposecretion of adrenaline, we can infer that the heat acts by depressing the secretion of adrenaline. Let us then compare the effects upon the human organism of cold and adrenaline, on the one hand, and of heat and absence of adrenaline on the other.
